Dedico esse trabalho a todos aqueles que destinam
sua vida ao desenvolvimento da ciência.

AGRADECIMENTOS

Primeiramente gostaria de agradecer a Deus e nossa Senhora Aparecida, sempre presentes em minha vida, principalmente nos momentos mais difíceis onde não existe onde se parar além da fé.

À Universidade Federal de São Carlos – UFSCar e o Programa de pós Graduação em Biotecnologia – PPG-Biotec por terem proporcionado a realização desta importante etapa da minha formação profissional.

Aos meus pais Ivo e Neide e minha irmã Ivone por todo o apoio durante todos esses anos de vida de pós graduando.

Aos membros da banca de defesa por terem aceitado o convite para participar de minha avaliação, contribuindo assim uma melhor interpretação dos resultados e desdobramentos deste trabalho.

À Fundação de Amparo a Pesquisa do Estado de São Paulo – FAPESP, pelo auxílio financeiro em forma de bolsa, ao projeto CEPID – Redoxoma e ao projeto Temático L-Asparaginase pelo auxílio financeiro.

Ao professor Dr. Marcos Antonio de Oliveira pela orientação, meu muito obrigado por todos esses anos de paciência, ajuda na interpretação de dados que pareciam interpretáveis. Foi um prazer inenarrável!!!

À Universidade Estadual Paulista - Campus Litoral Paulista por ter disponibilizado a estrutura necessária para realização deste trabalho.

Ao Prof. Dr. Marcos Toyama por ter disponibilizado a estrutura do seu laboratório para realização dos experimentos de SEC e também ao amigo Henrique Gaheta por toda a ajuda necessária para realização dos experimentos e interpretação dos dados.

Ao Prof. Dr. Luis Eduardo Soares Netto por ter disponibilizado a estrutura de seu laboratório para realização de experimentos, além de dicas e sugestões para melhorar o trabalho.

Ao Laboratório Nacional de Pesquisa de Energia e Materiais por disponibilizar a estrutura necessária para experimentos de cristalização, difração de cristais e microscopia eletrônica de transmissão. Além de ter me proporcionado a realização de cursos de alto nível indispensáveis para minha formação.

Aos pesquisadores Dr. Rodrigo Villares Portugal e Dr. Alexandre Cassago pela ajuda na realização dos experimentos de microscopia eletrônica de transmissão.

A todos os colegas do LABIMES um muito obrigado !!!! Já são tantos anos e tantas pessoas que até é difícil lembrar os nomes!!!! Carlão, Melina, Gnomo, Quebra, Gabriela, Papeixe, Werner, Findi, Livia, Felipe, Carla, Renata, Larissa, Nicholas entre outros.....Valeu Labimes!!!

Aos Carlos Tairum, Renata Fernandes, Felipe Zurlo e Danila R. Truzzi pela realização dos experimentos de experimentos de fluorescência.

Ao Dr. Antonio Romero responsável pelo laboratório de cristalografia de proteínas Centro de Investigaciones Biologicas (Madrid/Espanha) pela oportunidade da realização de estágio em um dos grupos referencia mundial na área de cristalografia de proteínas. Ao Dr. Javier Medrano Martim pela orientação durante esse estágio, pelas dicas imprescindíveis para a realização de experimentos que melhoraram muito meu trabalho e melhoraram minha forma de trabalhar.

Ao Diamond Light Source (Oxfordshire/Inglaterra) pela utilização da linha B21 para realização de experimentos de SAXS.

E a todos as pessoas que estiveram presentes em minha vida durante os últimos anos, seja nos momentos de descontração ou dias de intenso trabalho, Obrigado !!!!!!

Eu aprendi...

...que ignorar os fatos não os altera;

Eu aprendi...

...que quando você planeja se nivelar com alguém, apenas está permitindo que essa pessoa continue a magoar você;

Eu aprendi...

...que o AMOR, e não o TEMPO, é que cura todas as feridas;

Eu aprendi...

...que ninguém é perfeito até que você se apaixone por essa pessoa;

Eu aprendi...

...que a vida é dura, mas eu sou mais ainda;

Eu aprendi...

...que as oportunidades nunca são perdidas; alguém vai aproveitar as que você perdeu.

Eu aprendi...

...que quando o ancoradouro se torna amargo a felicidade vai aportar em outro lugar;

Eu aprendi...

...que não posso escolher como me sinto, mas posso escolher o que fazer a respeito;

Eu aprendi...

RESUMO

Peroxirredoxinas (Prx) são proteínas antioxidantes capazes de decompor uma grande variedade de hidroperóxidos, são muito abundantes na célula e em eucariotos estão distribuídas nos diversos compartimentos celulares. As Prx são capazes de reduzir seus substratos utilizando um resíduo de cisteína altamente reativa, denominada de cisteína peroxidásica (C_P-S^-), que se apresenta na forma de tiolato. No processo de decomposição de hidroperóxidos é oxidada a cisteína ácido sulfênico (C_P-SOH). A grande maioria destas proteínas se apresenta como dímeros obrigatórios e apesar de algumas Prx apresentarem somente uma cisteína, grande parcela possui uma segunda cisteína envolvida no ciclo catalítico que recebe o nome de cisteína de resolução (C_R), a qual forma um dissulfeto com C_P , que frequentemente é reduzido pela enzima tiorredoxina (Trx). Adicionalmente à redução das Prx, as Trx estão envolvidas em diversos outros processos biológicos como crescimento celular, inibição de apoptose, ativação de transcrição e síntese de DNA. Quando a célula é exposta a elevado estresse oxidativo, pode ocorrer a superoxidação de C_P formando espécies superoxidadas como a cisteína ácido sulfínico (C_P-SO_2H) e sulfônico (C_P-SO_3H) que não podem ser reduzidas por Trx. Entretanto, também resulta na alteração da estrutura quaternária das Prx, levando à formação de estruturas de alto peso molecular (HMW) que possuem propriedade de chaperona molecular e estão relacionadas a transdução de sinal desencadeada por hidroperóxidos. Em *Saccharomyces cerevisiae*, há duas isoformas citosólicas de Prx (Tsa1 e Tsa2), que possuem grande semelhança (86% de identidade e 96% de similaridade), mas apresentam diferenças na concentração celular e nível de expressão. Entretanto, muitas vezes são consideradas proteínas redundantes. Este trabalho teve como objetivos uma análise comparativa aprofundada buscando um maior entendimento das diferenças funcionais e estruturais de Tsa1 e Tsa2. Foram avaliados a relação de Tsa1 e Tsa2 com seus substratos oxidantes (hidroperóxidos) e substratos redutores (Trx1 e Trx2). Análises estruturais e cinéticas demonstraram uma importante relação entre a manutenção da estrutura decamérica a atividade das enzimas a qual ocorre por uma série interações polares similares mas não iguais entre aminoácidos do sítio ativo. Com destaque para a Thr44 de Tsa1 (Ser em Tsa2) que possui importância na estabilização da estrutura decamérica através de uma interação do tipo C-H-π com Tyr⁷⁷ e através do átomo de Oγ que possui interações polares com Phe⁴⁵ e Leu⁴¹. Também foram realizadas análises de susceptibilidade a superoxidação de Tsa1 e Tsa2, e demonstrou-se que peróxidos orgânicos são capazes de promover mais eficientemente a superoxidação quando comparados a H₂O₂, sendo que Tsa1 apresenta uma maior sensibilidade a superoxidação. Essa diferença foi também relacionada à substituição Thr/Ser e análises de susceptibilidade a superoxidação dos mutantes Tsa1^{T44S} e Tsa2^{S44T} demonstraram que a substituição reciproca tornou Tsa1^{T44S} mais resistente a superoxidação e Tsa2^{S44T} mais sensível. A formação de estruturas de alto peso molecular (HMW) de Tsa1, Tsa2 e mutantes foram investigadas através de cromatografia de exclusão molecular (SEC) e microscopia eletrônica de transmissão (TEM). Os resultados demonstraram um aumento da formação de HMW após reações de superoxidação utilizando o sistema Trx em altas concentrações de CHP e foi verificada a presença de empilhamentos de decâmeros, além de esferas, descritas na literatura. Os resultados obtidos neste trabalho demonstram de forma clara que as proteínas Tsa1 e Tsa2 diferem de forma significativa tanto na suscetibilidade a superoxidação quanto na formação de complexos HMW distintos, indicando fortemente que estas proteínas possuem papéis biológicos não redundantes e que alterações sutis de aminoácidos no sítio ativo promovem grandes alterações funcionais e estruturais nas enzimas.

Palavras chave: Peroxirredoxinas. Reatividade. Superoxidação. Estruturas de alto peso molecular.

ABSTRACT

Peroxiredoxins (Prx) are antioxidant proteins capable of decomposing a variety of hydroperoxide are very abundant in the cell and in eukaryotes are distributed in many cell compartments. The Prx are able to reduce their substrates using a highly reactive cysteine residue, named peroxidatic cysteine (C_P -S \cdot), which is maintained in the thiolate form as a consequence of the active site environment. In hydroperoxide decomposition process the C_P is oxidized to cysteine sulfenic acid (C_P -SOH). These vast majorities of these proteins are obligate dimers and has a second cysteine involved in the catalytic cycle, named resolution cysteine (C_R), which forms a disulfide with C_P and is often reduced by the enzyme thioredoxin (Trx). In addition to the reduction of Prx, the Trx are involved in several other biological processes such as cell growth, inhibition of apoptosis, transcriptional activation and DNA synthesis. When cell are exposed to oxidative stress, the CP can suffer overoxidation, forming species such as cysteine sulfinic acid (C_P -SO₂H) and cysteine sulfonic acid (C_P -SO₂H), which are not reduced by Trx. However, the C_P overoxidation results in a change of the of Prx quaternary structure, resulting in the formation of high molecular weight structures (HMW) with molecular chaperone property and related to signal transduction triggered by hydroperoxides. *Saccharomyces cerevisiae*, have two isoforms of cytosolic Prx (Tsa1 and Tsa2), which shares high similarity (86% identity and 96% similarity), but differ in cellular abundance and expression levels. However, these enzymes are often considered redundant proteins. This study aimed the comparative analysis searching for functional and structural differences between Tsa1 and Tsa2. We evaluated Tsa1 and Tsa2 relationships with its oxidizing (hydroperoxide) and reducing substrates (Trx1 and Trx2). We also performed structural and kinetic analysis showed a significant relationship between maintaining the decameric structure the activity of enzymes which occurs by a series polar interactions but not equal to the active site amino acids. Highlighting the Thr44 of Tsa1 (Ser in Tsa2) which is involved in decamer structure stabilization by a CH-π interaction type with the Tyr77 and through the Oy atom (from Thr) polar interactions with Phe45 and Leu41. Overoxidation susceptibility assays were performed using Tsa1 and Tsa2, and our results revealed that organic hydroperoxides were able to promote the C_P overoxidation more efficiently when compared to H₂O₂. In turn, Tsa2 was very more resistant to C_P overoxidation than Tsa1. This difference was also investigated concerning the catalytic triad Thr (Tsa1) to Ser (Tsa2). We generated mutants carrying reciprocal substitutions Tsa1^{T44S} and Tsa2^{S44T} and our results revealed that Tsa1^{T44S} become more resistant to C_P overoxidation and Tsa2^{S44T} become more sensitive. The formation of high molecular weight structures (HMW) of Tsa1, Tsa2 and mutants were also investigated by size exclusion chromatography (SEC) and transmission electron microscopy (TEM). The Tsa1, Tsa2 and mutants HMW formation were analyzed by size exclusion chromatograph (SEC) and transmission electron microscopy (TEM). The results showed an increase of HMW formation after Trx system reaction using high concentrations of CHP. Were observed the stacking of the ring-shaped structures besides spherical species. Our results demonstrate that Tsa1 and Tsa2 proteins differ significantly in overoxidation susceptibility and HMW complex formation, indicating that these proteins have not redundant biological roles and small changes in active site promote high functional and structural changes in these enzymes.

Keywords: Peroxiredoxins, Overoxidation, Reactivity, High Molecular Weight Complexes.

LISTA DE ABREVIATURAS

$\cdot\text{OH}$	Radical hidroxila
AhpC	Alquil hidroperóxido redutase subunidade C
Cat	Catalases
CHP	Cumeno hidroperóxido
C_P	Cisteína peroxidásica
$\text{C}_\text{P}\text{-S}^-$	Tiolato
C_R	Cisteína de resolução
Cys-SO ₂ H	Ácido sulfínico
Cys-SO ₃ H	Ácido sulfônico
Cys-SOH	Ácido sulfênico

1 INTRODUÇÃO

1.1 Espécies Reativas de Oxigênio

Espécies reativas de oxigênio (EROs) são formadas durante o metabolismo normal de organismos aeróbicos através da redução incompleta do oxigênio molecular, seu acúmulo em um organismo pode levar ao chamado estresse oxidativo (Halliwell; e Gutteridge, 2007). Estresse oxidativo pode ser definido como um desequilíbrio entre a produção de EROS e a capacidade de um organismo decompor essas espécies (Freinbichler *et al.*, 2011; Halliwell e Gutteridge, 1990). A ocorrência de estresse oxidativo tem sido relacionada há várias patologias, incluindo doenças neurodegenerativas, lesões cerebrais traumáticas ou isquêmicas, câncer, diabetes, lesões hepáticas e AIDS (Finkel, 2003; Halliwell e Gutteridge, 1990; Valko *et al.*, 2006). Também se acredita que o estresse oxidativo pode desempenhar um papel importante no processo de envelhecimento (Boisnard *et al.*, 2009; Dalle-donne *et al.*, 2007; Freinbichler *et al.*, 2011; Nelson *et al.*, 2011a).

Dentre as EROS, grande destaque dá-se ao peróxido de hidrogênio (H_2O_2), radical ânion superóxido ($O_2^{\cdot-}$) e o radical hidroxila ($\cdot OH$). A cadeia transportadora de elétrons consiste no principal processo metabólico responsável pela geração de EROS, sendo que cerca de 0.1 a 5% do oxigênio molecular escapa na forma de $O_2^{\cdot-}$ e H_2O_2 (Halliwell e Gutteridge, 2015). Algumas destas espécies podem transitar livremente nas células, como exemplo o $O_2^{\cdot-}$, que apesar da sua baixa permeabilidade pela membrana lipoproteica consegue atravessá-la por canais aniônicos e reagir com grupos prostéticos metálicos de proteínas (Halliwell e Gutteridge, 2015; Sies, 2014). O H_2O_2 , por sua vez, pode se difundir pelas membranas celulares, ou mesmo ser transportado através de canais homólogos às aquaporinas (Bienert, Schjoerring e Jahn, 2006; Bienstock, 2011; Malinouski *et al.*, 2011; Miller, Dickinson e Chang, 2010) e é um oxidante proteico, em especial, de resíduos de metionina e cisteína (Kang *et al.*, 2005). Apesar de não ultrapassar as membranas celulares, o radical $\cdot OH$ é extremamente reativo e pode danificar lipídeos, ácidos nucléicos, proteínas e outros compostos orgânicos (Halliwell e Gutteridge, 2015; Valko *et al.*, 2006). O radical $\cdot OH$ pode ser formado a partir de reações entre o $O_2^{\cdot-}$ e o H_2O_2 com metais de transição por meio da reação de Fenton (1) ou diretamente através da reação de Harber-Weiss (2) (Halliwell e Gutteridge, 2015; Kehrer, 2000).

Através do processo evolutivo, os organismos desenvolveram diferentes estratégias para impedir a formação e decompor as EROs e adicionalmente, passaram também a utilizar estas espécies na defesa e sinalização celular (Halliwell e Gutteridge, 2015; Mittler *et al.*, 2011). Desta forma, enzimas como as lipoxygenases, NAD(P)H oxidases, xantina desidrogenase, entre outras, são capazes de produzir EROs, as quais podem desempenhar importantes papéis na sinalização celular (Halliwell e Gutteridge, 2007). Segundo Mittler e colaboradores (2011), várias são as vantagens da utilização destas moléculas em sinalização celular. Dentre elas, destaca-se a capacidade da célula rapidamente produzir e degradar estas espécies de forma simultânea, permitindo assim mudanças rápidas em seus níveis de forma dinâmica. Outra vantagem seria um controle específico sobre a localização subcelular de sinais de EROs nas células (Mittler *et al.*, 2011). EROs controlam importantes eventos celulares em eucariotos, uma vez que agem como mensageiras para a transdução de sinal e controle da expressão gênica (Gamaley e Klyubin, 1999; Kamata e Hirata, 1999; Kang *et al.*, 2005; Pastorí e Foyer, 2002) sendo o H₂O₂ um componente essencial desse processo (Toledano, Planson e Delaunay-Moisan, 2010). O H₂O₂ é capaz de oxidar resíduos de cisteína presentes em proteínas que agem como sensores, levando à formação do ácido sulfênico (Cys-SOH), sulfônico (Cys-SO₂H) ou sulfônico (Cys-SO₃H) e ocasionando mudanças estruturais de proteínas que respondem pela especificidade da sinalização celular (Chiu *et al.*, 2011; Kumsta e Jakob, 2009; Poole, Karplus e Claiborne, 2004). É importante ressaltar que concentrações intracelulares superiores a 1 μM de H₂O₂ são tóxicas às células e ineficazes para os propósitos reguladores (Antunes, Cadenas e Brunk, 2001).

As enzimas responsáveis pela degradação das EROs podem ser divididas em dois grandes grupos principais. O primeiro se caracteriza pela conversão de radicais superóxido (O₂^{•-}) a peróxido de hidrogênio (H₂O₂), o qual é efetuado pela enzima superóxido dismutase (SOD) (Kato *et al.*, 1999). O segundo é capaz de decompor o H₂O₂ e suas principais representantes são as catalases (Cat), as glutationas peroxidases (Gpx) e as peroxirredoxinas (Prx) (Figura 1) (Halliwell e Gutteridge, 2015; Kang *et al.*, 2005).

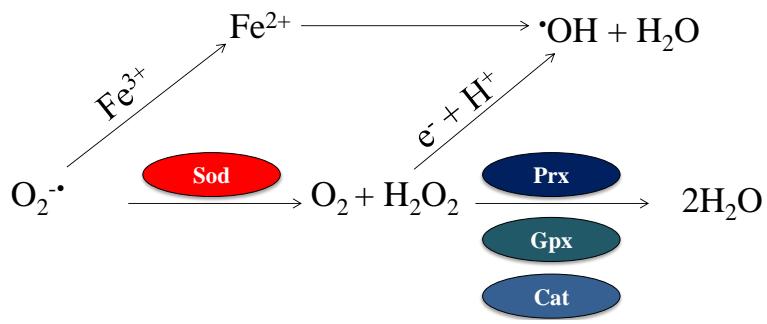

Figura 1. Formação e decomposição enzimática de espécies reativas de oxigênio. Processo de formação de algumas das espécies reativas de oxigênio mais abundantes nos organismos e as principais enzimas antioxidantes envolvidas na sua decomposição.

1.2 Peroxirredoxinas

As Peroxirredoxinas (Prx), também denominadas de tiorredoxinas peroxidases (Tpx), tem despertado o interesse de muitos pesquisadores voltados à compreensão dos mecanismos celulares antioxidantes, uma vez que estas são muito abundantes e largamente distribuídas nos mais diversos compartimentos celulares (Demasi, Pereira e Netto, 2001; Flohé e Harris, 2007). As Prx compreendem uma ampla família de peroxidases portadoras de grupamentos tiol, que são utilizados na redução dos substratos (Dietz, 2007; Hofmann, Hecht e Flohé, 2002; Lukosz *et al.*, 2010; Wood *et al.*, 2003). Todas elas possuem ao menos um resíduo de cisteína na porção N-terminal, denominada de cisteína peroxidásica (C_P), correspondente ao sítio de oxidação dos hidroperóxidos. Estas enzimas são encontradas em praticamente todos os organismos e largamente investigadas na levedura *Saccharomyces cerevisiae*, devido à alta similaridade entre as enzimas deste organismo e as de mamíferos.

As Prx podem ser subdivididas em três grupos distintos quanto às estruturas proteicas e pelo número de cisteínas presentes em seus sítios ativos (SA): as 1-Cys Prx são proteínas diméricas que apresentam apenas um resíduo de cisteína na região N-terminal; as 2-Cys típicas, também diméricas, com dois resíduos de cisteína dispostos nas regiões N e C-terminais. Estes durante o ciclo catalítico formam dissulfeto intermolecular e, finalmente, as 2-Cys atípicas, que se apresentam como monômeros e também possuem dois resíduos de cisteína que durante o ciclo catalítico formam ponte dissulfeto intramolecular (Choi *et al.*, 2005; Hall, Karplus e Poole, 2009; Hall *et al.*, 2009).

Recentemente uma nova classificação foi proposta para as Prx que leva em consideração o aspecto estrutural e aminoácidos conservados em torno do sítio ativo. Baseados nessa disposição as Prx são classificadas em seis subfamílias: AhpC-Prx1, BCP-PrxQ, Tpx, Prx5, Prx6 e AhpE. Todos os representantes das 2-Cys típicas, que são objeto deste estudo, foram incluídos na subfamília AhpC-Prx1 (Nelson *et al.*, 2011b).

Adicionalmente às formas diméricas, já foram observadas estruturas decaméricas de Prx 2-Cys típicas as quais são estabelecidas através da associação de cinco dímeros resultando na formação de decâmeros do tipo α_2 [5]. Alguns autores sugerem que esta organização poderia levar a decomposição cooperativa de moléculas de peróxido, semelhante ao caso muito bem estudado da molécula de hemoglobina (Cox e Nelson, 2008; Tairum *et al.*, 2015). Desta forma, a decomposição de peróxidos por uma subunidade do decâmero poderia aumentar a afinidade por peróxidos das demais subunidades (Cox *et al.*, 2009; Parsonage *et al.*, 2005). Aspectos adicionais referentes ao estado de oligomerização das Prx 2-Cys típicas serão discutidos posteriormente.

No processo de decomposição dos hidroperóxidos pelas Prx 2-Cys típicas, a cisteína peroxidásica (C_P) é oxidada e forma uma cisteína ácido sulfênico ($C_P\text{-SOH}$) que reage com o H da cisteína de resolução (C_R) do monômero adjacente, formando uma ligação dissulfeto intermolecular entre as cisteínas e eliminando H_2O (Chae, Ho Zoon, Chung e Rhee, 1994; Collin *et al.*, 2003; Hall, Karplus e Poole, 2009; Perkins *et al.*, 2015; Poole, Hall e Nelson, 2011; Wilson *et al.*, 1998; Wood *et al.*, 2003) (Figura 2).

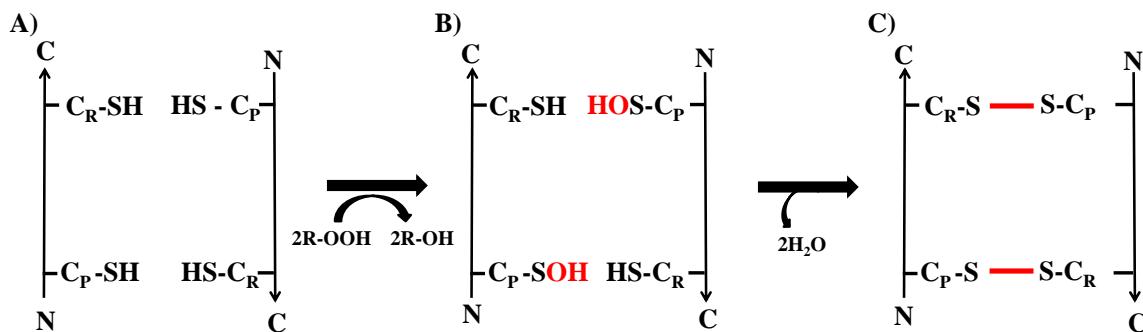

Figura 2. Mecanismo de decomposição de hidroperóxidos pelas Prx 2-Cys típicas. A) Inicialmente as cisteínas peroxidásicas dos diferentes monômeros reagem com moléculas de hidroperóxido. No caso de reação com um peróxido orgânico, ocorre à liberação de um álcool ou água se a reação ocorrer com H_2O_2 . B) Após a reação as C_P são oxidadas a cisteína ácido sulfênico ($C_P\text{-SOH}$). C) Ocorre uma reação de condensação liberando H_2O e formam-se ligações dissulfeto entre C_P e C_R dos diferentes monômeros.

As Prx diferentemente de outras proteínas antioxidantes não requerem cofatores para sua atividade catalítica. Durante a catálise a C_P é mantida na forma de tiolato ($C_P\text{-S}^-$) em um motivo conservado PXXXTXXC (em alguns casos a T pode ser substituído por S), ao reagir com um hidroperóxido o tiolato fica oxidado na forma de C_P -ácido sulfênico ($C_P\text{-SOH}$). Após a reação ocorre à formação de um dissulfeto intramolecular (2-Cys Prx típicas), intermolecular (2-Cys Prx atípicas) ou a forma $C_P\text{-SOH}$ é diretamente reduzida (1-Cys Prx). Normalmente grupos sulfidrila de proteínas em sistemas biológicos tendem a ser manter protonados (tiol, R-SH), pois o pK_a da Cys é de 8.5 acima do pH neutro. Mas muitas vezes o pK_a dos resíduos de Cys pode ser influenciado pelo microambiente do sítio ativo e ser

estabilizado na forma de tiolato, sendo que o pK_a observado para diferentes Prx varia de 5.1 a 6.3. Sendo assim, estas proteínas mesmo em pH 7.0 apresentam-se ativas na forma C_P-S^- .

Recentemente através de análises estruturais e trabalhos computacionais foi proposto um mecanismo de catálise para as Prx baseado nas características do sítio ativo. Neste mecanismo a Prx reage com o peróxido (HO_A-O_BR) através de uma substituição nucleofílica (S_N2), o tiolato ataca o oxigênio terminal (O_A) do hidroperóxido, levando quebra da ligação entre O_A-O_B , e a formação da C_PSOH (Figura 3A). Neste mecanismo também é proposto à participação dos resíduos de Thr e Arg os quais orientam a entrada do hidroperóxido no sítio ativo através de duas ligações de hidrogênio. Após o direcionamento do hidroperóxido no sítio ativo ocorre a estabilização do chamado estado de transição ($C_P - S\gamma^{\cdot\cdot}O_A$), forma-se C_PSOH e ocorre a saída do grupo abandonador (O_BR) (Hall *et al.*, 2010; Perkins *et al.*, 2015).

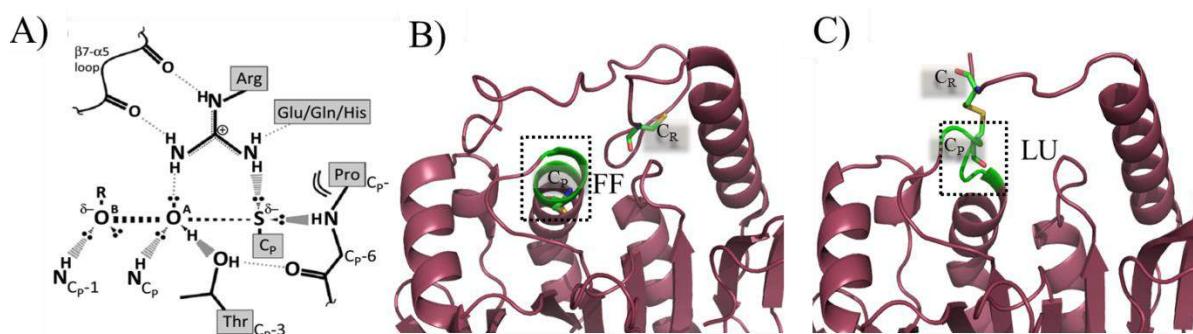

Figura 3. Mecanismo de reação proposto para as 2-Cys Prx e representação das conformações FF e LU. A) Representação em *cartoon* do mecanismo de reação, neste o hidroperóxido é direcionado ao tiolato através de ligações de H com a Thr e Arg, assim ocorre à reação do O_A com o tiolato levando a formação de SOH e liberação do grupo abandonador (O_BR) (Compilado de Perkins *et al.* 2015). B) Representação do estado *Fully folded* (FF) da proteína AhpC de *S. typhimurium* na forma reduzida (código PDB: 4MA9). C) Representação do estado *Locally unfolded* (LU) da proteína AhpC de *S. typhimurium* na forma oxidada (código PDB: 1YEP). Nas figuras B e C a região que sofre um desenovelamento parcial é destacada pelo retângulo pontilhado. A C_P e C_R são representadas no modo *sticks* coloridas por CPK (C: verde; O: vermelho, N: azul e S: laranja). As figuras B e C foram geradas através do programa pyMOL.

Após a reação com um hidroperóxido nas 2-Cys Prx ocorre a formação de uma ligação dissulfeto entre a C_P e C_R . Para que ocorra essa ligação é necessário o desenovelamento parcial de uma α -hélice (Figura 3B e 3C). Neste contexto, quando a C_P encontra-se reduzida a α -hélice encontra-se enovelada em uma conformação denominada de *fully folded* (FF), após a reação com um hidroperóxido ocorre o desenovelamento parcial da α -hélice e formação de dissulfeto, essa conformação é denominada *locally unfolded* (LU).

1.3 Redução das Prx: O Sistema Tiorredoxina

Para realizar um novo ciclo catalítico, o dissulfeto das Prx necessita ser reduzido. A Tiorredoxina (Trx) é o substrato da maioria das peroxirredoxinas e, além desta função, as Trx

estão envolvidas em diversos outros processos biológicos como crescimento celular, inibição de apoptose, ativação de transcrição e síntese de DNA. Trx foi inicialmente identificada em *E. coli* por Peter Reichard e colegas, em 1964, como o redutor da ribonucleotídeo redutase a qual é essencial para a síntese de DNA. Posteriormente também foi demonstrado seu envolvimento no ciclo de alguns bacteriófagos e em células eucarióticas é também um doador de elétrons para a ribonucleotídeo redutase como também da 3'-5'-fosfoadenosina fosfato redutase e metionina-sulfóxido redutase. Além de ser um antioxidante capaz de reduzir com baixa eficiência o H₂O₂, entretanto, seu principal papel antioxidant ocorre por meio da redução das Prx (Pedrajas *et al.*, 2000). Membros da superfamília Trx estão envolvidos em reações tiól-dissulfeto e possuem em seus sítios ativos o motivo C-X-X-C. Neste motivo a cisteína reativa é localizada na região N-terminal e a natureza dos aminoácidos entre as duas cisteínas varia consideravelmente entre os membros da superfamília, influenciando o pK_a das cisteína e, consequentemente, as propriedades redox destas proteínas (Pedone *et al.*, 2010). Após a redução das Prx ou outro alvo biológico, as cisteínas de Trx são oxidadas a dissulfeto.

TrxR catalisa a redução do dissulfeto da Trx oxidada utilizando uma molécula de nicotinamida adenina dinucleotídeo fosfato (NADPH) via dois centros redox: um FAD e um motivo contendo duas cisteínas vicinais. Neste contexto, a flavina transfere equivalentes redutores da molécula de NADPH para a ponte dissulfeto de suas cisteínas e destas para as cisteínas oxidadas de Trx (Dai *et al.*, 1996; Waksman *et al.*, 1994) (Figura 4). NADPH, TrxR e Trx compreendem o sistema redutor denominado de sistema tiorredoxina (Holmgren e Lu, 2010).

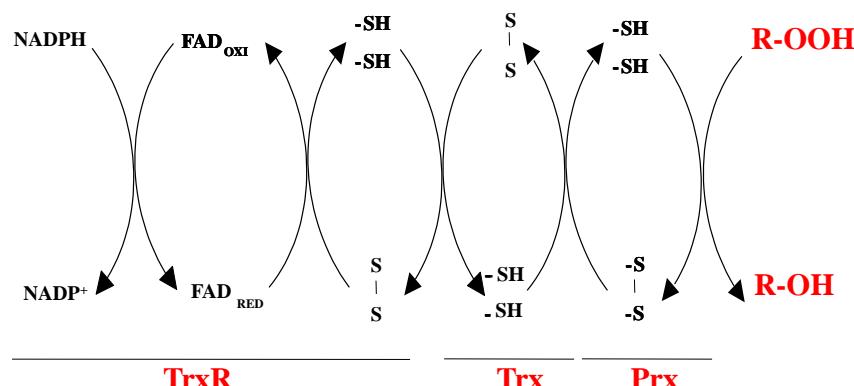

Figura 4. Relação redox das Prx com o sistema redutor tiorredoxina. Prx na forma reduzida reage com um peróxido, liberando H₂O, no caso da redução de H₂O₂, ou um álcool, no caso de peróxidos orgânicos, tornando-se oxidada. Neste momento é formada uma ligação dissulfeto entre as duas cisteínas de Prx. Prx oxidada é reduzida por Trx que se oxida e, por sua vez, é reduzida pela proteína TrxR (Tiorredoxina redutase) com elétrons provenientes do NADPH.

As Prx possuem o mecanismo catalítico do tipo Bi Bi Ping Pong, desta forma, a enzima possui dois substratos (o hidroperóxido e a tiorredoxina reduzida), produz dois

produtos (H_2O ou um derivado álcool, no caso de peróxidos orgânicos, e a tiorredoxina oxidada) e a liberação de produto ocorre de forma intercalada à entrada de substrato no sitio ativo (Figura 5) (Baker *et al.*, 2001).

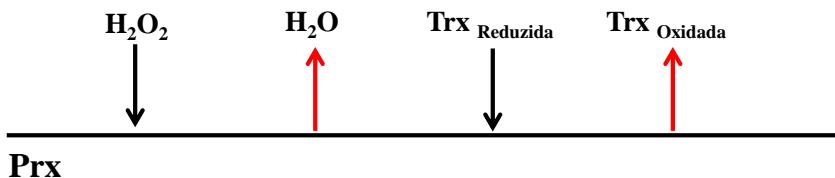

Figura 5. Representação do mecanismo catalítico do tipo Bi Bi Ping Pong das Prx. Prx inicialmente reage com um peróxido, no caso H_2O_2 , liberando água. Posteriormente reage com Trx recuperando sua forma reduzida.

1.4 Formação de complexos supramoleculares de peroxirredoxinas

Foi demonstrado que quando submetidas a choques térmicos ou ao estresse oxidativo as Prx 2-Cys típicas são capazes de se associar em estruturas de alto peso molecular (*High Molecular Weight - HMW*). Inicialmente foi demonstrado que estas espécies possuíam uma atividade de chaperona molecular que ocorre em concerto com a perda de sua atividade peroxidásica (Aran *et al.*, 2011; Jang *et al.*, 2004; Kumsta e Jakob, 2009). Como mencionado anteriormente, as Prx 2-Cys típicas são dímeros obrigatórios; entretanto, quando ocorre a transição de função peroxidásica → chaperona, os dímeros (~ 40kDa) se associam e formam decâmeros ou complexos com peso molecular mais elevado (>1000 kDa) (Aran *et al.*, 2011; Jang *et al.*, 2004; Kumsta e Jakob, 2009; Saccoccia *et al.*, 2012). Vale ressaltar que essa alteração estrutural só foi detectada para as Prx do grupo 2-Cys típicas (Jang *et al.*, 2004) (Jang e col., 2004). A figura 6 ilustra algumas estruturas quaternárias detectadas para as Prx.

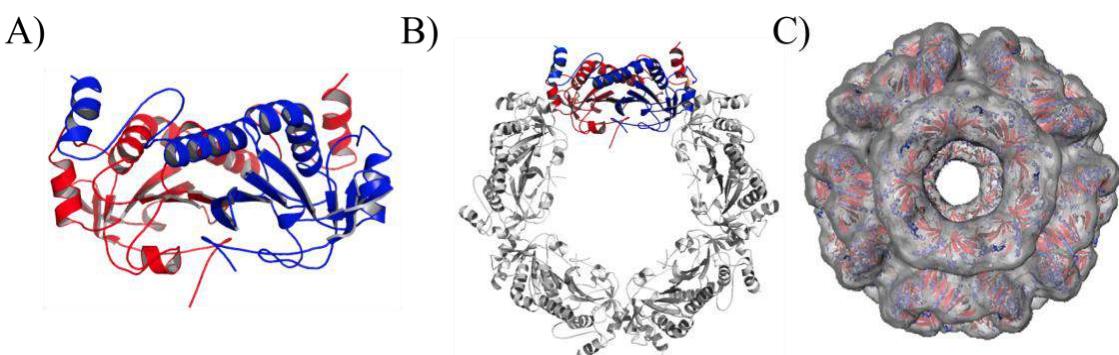

Figura 6. Diferentes estruturas quaternárias apresentadas por Prx 2-Cys típicas. A) Dímero de Tsa1 de levedura. Um monômero é colorizado em azul e o monômero adjacente em vermelho. B) União de cinco dímeros de Tsa1 formando uma estrutura de decâmero onde o dímero superior está colorizado em azul e vermelho e o restante dos dímeros estão representados em cinza. C) União de 12 estruturas decaméricas formando uma estrutura dodecaédrica detectada para Prx2 de humanos. Imagens A e B gerada por PyMOL (<http://www.pymol.org/>) e imagem C compilada de Meissner *et al.*, 2004.

O processo de oligomerização por choque térmico ainda não é bem compreendido, porém, o processo de resposta ao estresse oxidativo é reconhecidamente baseado em

alterações estruturais resultantes da superoxidação de C_P (Jang *et al.*, 2004; Lim *et al.*, 2008). Em situações de alta concentração de H₂O₂, as C_P sofrem superoxidação e são convertidas em cisteína ácido sulfínico (C_P-SO₂H) ou cisteína ácido sulfônico (C_P-SO₃H) que culminam na alteração estrutural das enzimas. No caso de superoxidação, as Prx não podem ser recicladas pelas tiorredoxinas (Trx), mas de forma alternativa uma segunda enzima denominada sulfirredoxina (Srx) assume o papel na redução enzimática das Prx, sendo capaz de reduzir somente a forma cisteína ácido sulfínico (C_P-SO₂H) (Biteau, Labarre e Toledano, 2003). Contudo, até o presente momento, não se conhece redutor biológico para a forma C_P-SO₃H, porém dados demostram que a formação de C_P-SO₃H é facilitada em condições *in vivo*, sugerindo a existência de fatores desconhecidos envolvidos nessa transição (Lim *et al.*, 2008).

Adicionalmente, diversos estudos apontam que a superoxidação das 2-Cys Prx também representa um mecanismo de defesa indireto através da Trx. Uma vez que as 2-Cys Prx estão entre as proteínas mais abundantes das células (Chemical *et al.*, 2003; Wood, Poole e Karplus, 2003) e há transdução de sinal envolvendo o H₂O₂ (Kumsta e Jakob, 2009; Toledano *et al.*, 2005; Vivancos *et al.*, 2006). De fato a redução das Prx implica no acúmulo de Trx na forma oxidada, o que é fundamental em diversos processos de transdução de sinal, os quais não ocorrem quando a Trx se encontra reduzida (Holmgren *et al.*, 2005; Perkins *et al.*, 2015). A oxidação direta da Trx por hidroperóxidos é lenta (Chae, H Z, Chung e Rhee, 1994) (Chae, Chung, Rhee, 1994) e, pelo fato das Prx serem altamente abundantes no ambiente celular, podendo representar 1% das proteínas solúveis na célula (Ghaemmaghami *et al.*, 2003), acredita-se que possuem grande relevância na oxidação das Trx *in vivo*.

Já foi demonstrado que a inativação da 2-Cys Prx de *Schizosaccharomyces pombe* permite que Trx permaneça reduzida e atue em mecanismos de reparo (Day *et al.*, 2012). Neste caso, em condições normais Trx1 se mantém reduzida possuindo como substratos além de Tpx1 (isoforma de Prx análoga a Tsa1 de *S. cerevisiae*) o fator de transcrição Pap1, que é responsável pelo controle da expressão de proteínas que combatem o estresse oxidativo e também é doadora de elétrons da proteína metionina sulfóxido redutase (Mxr1) na redução de resíduos de metionina (sulfóxido de metionina- Met-SOH) em proteínas danificadas por estresse. Em condições moderadas de estresse oxidativo Trx1 reduz preferencialmente Tpx1 promovendo assim uma adaptação da célula à condição de estresse oxidativo. Quando ocorre a exposição a altos níveis de hidroperóxidos, ocorre a superoxidação das C_P de Tpx1, o que permite que Trx1 seja substrato de Mrx1, permitindo o reparo de proteínas oxidadas, vital para a sobrevivência da célula (Day *et al.*, 2012) (Figura 7).

Outro exemplo se trata da ativação do NF-κB pela Trx1, o qual precisa ter os resíduos de cisteína reduzidos para que ocorra a ligação da subunidade p50 à sequência de DNA alvo (Hayashi, Ueno e Okamoto, 1993; Matthews *et al.*, 1992). Em mamíferos, apenas Trx1 reduzida é capaz de se ligar a MAPKKK Ask1 (*Apoptose signaling kinase*), uma proteína envolvida na sinalização de apoptose, inibindo a sua atividade de quinase, enquanto a oxidação de Trx1 leva à dissociação física do complexo e, consequentemente, à ativação de Ask1 (Liu *et al.*, 2000).

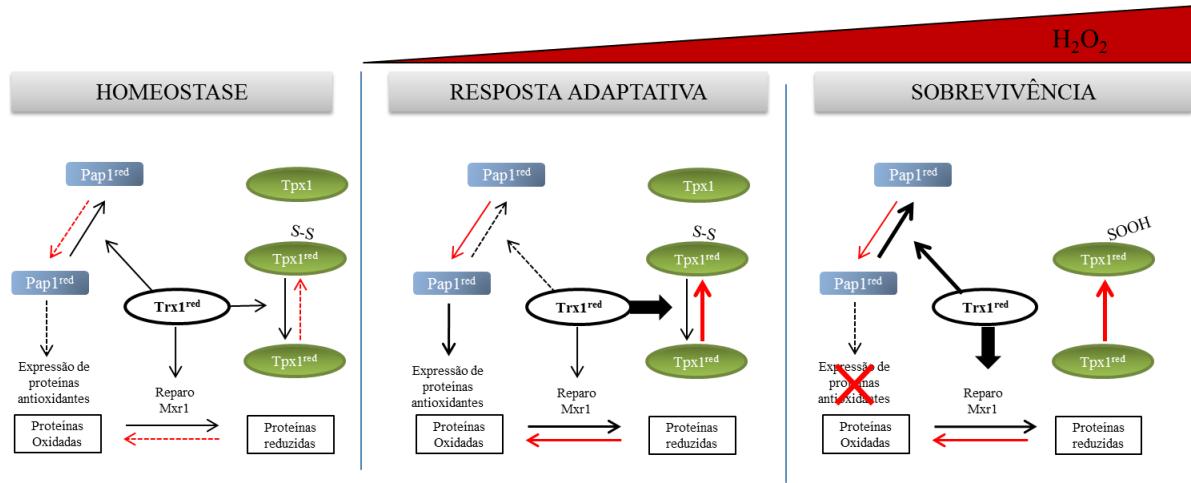

Figura 7: Respostas a H_2O_2 são iniciadas por mudanças no estado redox de Tpx1 e determinam a atividade de Trx1. Em condições homeostáticas normais Trx1 (Trx^{red}) mantém como substrato proteínas que incluem Tpx1, Mxr1, e Pap1, em um estado reduzido. Quando as células são expostas a níveis moderados de peróxido de hidrogênio, Trx1 torna-se mais oxidada devido ao seu envolvimento na remoção catalítica de peróxido de hidrogênio por Tpx1. Assim, a redução mediada Trx1 de outros substratos é inibida. Isto permite a acumulação de Pap1 oxidada. Juntas, essas respostas adaptativas (atividade peroxidásica de Tpx1, expressão do gene e reparação de proteína) podem agir juntas para restaurar a homeostase. Em níveis elevados de peróxido de hidrogênio, há um aumento dos danos oxidativos a proteínas e a redução de Pap1 é inibida e com isso não ocorre à expressão de genes antioxidentes. Nestas condições de estresse oxidativo Tpx1 fica superoxidata permitindo que Trx reduza outros substratos, tais como Mxr1. As setas vermelhas indicam as reações em que o peróxido de hidrogênio participa. A espessura de cada seta dá uma indicação qualitativa das taxas de reação cada condição, setas tracejadas indicam reações mínimas. As formas predominantes Pap1 e Tpx1 no âmbito de cada estado são indicados por contorno em negrito (Adaptado de Day *et al.*, 2012).

Recentemente também foi demonstrada a presença de uma interação física por meio de um dissulfeto transitório entre Prx2 de humanos e STAT3 (*Signal transducer and activator of transcription 3*), proteína que está envolvida na ativação de fatores de crescimento. Neste trabalho foi observado que a oxidação de STAT3 por Prx2 leva à formação de oligômeros de STAT3, os quais possuem atividade transcricional reduzida e, para que a enzima possa voltar a sua atividade máxima, é necessária sua redução pelo sistema tiorredoxina. Sendo assim, a superoxidação de Prx2 impede a formação do complexo STAT3-Prx2, impactando de forma direta e significativa as vias dependentes de STAT3 (Sobotta *et al.*, 2015). De forma geral, pode-se dizer que a inativação das Prx por superoxidação pode fazer com que ocorra um acréscimo na concentração local de peróxidos que poderiam reagir com outros alvos, além de

aumentar a quantidade de Trx reduzida, impactando nas vias de sinalização redox-dependentes (Day *et al.*, 2012; Wood, Poole e Karplus, 2003).

É interessante ressaltar que o trabalho pioneiro de Jang e colaboradores (2004) revelam que a superoxidação de Tsa1 e Tsa2, duas isoformas de Prx 2-Cys típicas de *S. cerevisiae*, assim como as enzimas Prx1 e Prx2 (homólogas de humanos) (Moon *et al.*, 2005), necessitam da ação das tiorredoxinas para que ocorra a superoxidação. Apesar de parecer contraditória, a necessidade da Trx ocorre por conta que a formação de um dissulfeto entre C_P e C_R, inviabiliza a superoxidação da cisteína peroxidásica em C_P-SO₂H ou C_P-SO₃H. Desta forma, a ação das Trx se torna imprescindível para que os dissulfetos das Prx sejam reduzidos, possibilitando nova exposição de C_P a hidroperóxidos, permitindo a formação de uma maior quantidade de espécies superoxidadas que podem se associar em estruturas de alto peso molecular (HMW) (Figura 8).

Um ponto importante a ser destacado com relação à superoxidação é o tempo de formação do dissulfeto, reações rápidas de formação de dissulfeto impedem a superoxidação. Já foi demonstrado que Prx3 de humanos é mais resistente a superoxidação que a isoforma Prx2, o que estaria fortemente relacionado com as constantes para formação de dissulfeto de Prx2 (1.7 s⁻¹) e Prx3 (22 s⁻¹) (Peskin *et al.*, 2013).

As diferenças encontradas nas taxas de formação de dissulfeto podem também estar relacionadas a presença de dois motivos hidrofóbicos (GGLG e YF), presentes em 2-Cys Prx típicas, localizados próximo a região C terminal os quais interagem entre si e interferem na dinâmica da formação de dissulfetos, no caso das diferenças de formação de dissulfeto entre Prx2 e Prx3 essa diferença é relacionada a outros aminoácidos presentes na região C-terminal (Cox, Pearson, Pullar, Jönsson, *et al.*, 2009; Lowther e Haynes, 2011; Hall *et al.*, 2009; Jang *et al.*, 2004).

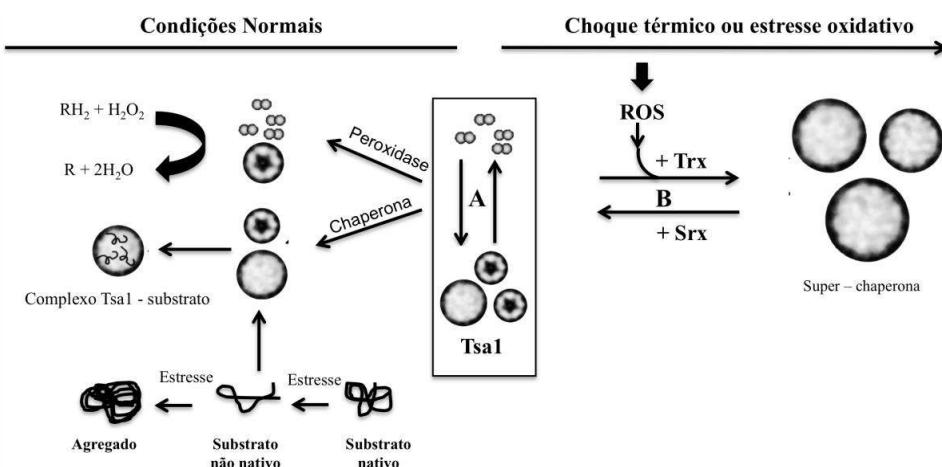

Figura 8. Modelo de formação de complexos HMW de Tsa1. Em baixos níveis de peróxidos hidroperóxidos (A) Tsa1 se apresenta na forma de dímero ou decâmero e atua na decomposição de peróxido. Em condições de

estresse oxidativo ou choque térmico (**B**) são formadas HMW com função de chaperona molecular e que estão envolvidas na sinalização redox. A formação destas estruturas HMW necessita da participação do sistema Trx, e as espécies superoxidadas ($C_P\text{-SO}_2\text{H}$) podem ser reduzidas pela enzima sulfiredoxina (Srx) (Adaptado de Jang *et al.*, 2004).

Saccoccia e colaboradores (2012) demonstraram também a atividade de chaperona molecular em SmPrxI de *Schistosoma mansoni*. Neste trabalho os autores determinaram a estrutura tridimensional de SmPrxI em sua forma decamérica (Figura 9A) com função peroxidásica e também na forma de duplo decâmero ao qual os autores sugerem ser a responsável pela função de chaperona molecular (Figura 9B) (Saccoccia *et al.*, 2012). Neste mesmo trabalho é sugerido através de um modelo teórico que SmPrxI forma estruturas na forma de filamentos formados a partir da sobreposição de decâmeros estes responsáveis pela função de chaperona molecular. Recentemente Radjaina e colaboradores (2015) utilizando crio-microscopia eletrônica resolveram a estrutura da Prx3 humana na forma de filamento (resolução de 7 Å), a qual também se acredita como a possível forma na qual a proteína atua como chaperona molecular (Saccoccia *et al.*, 2012) (Figura 9C).

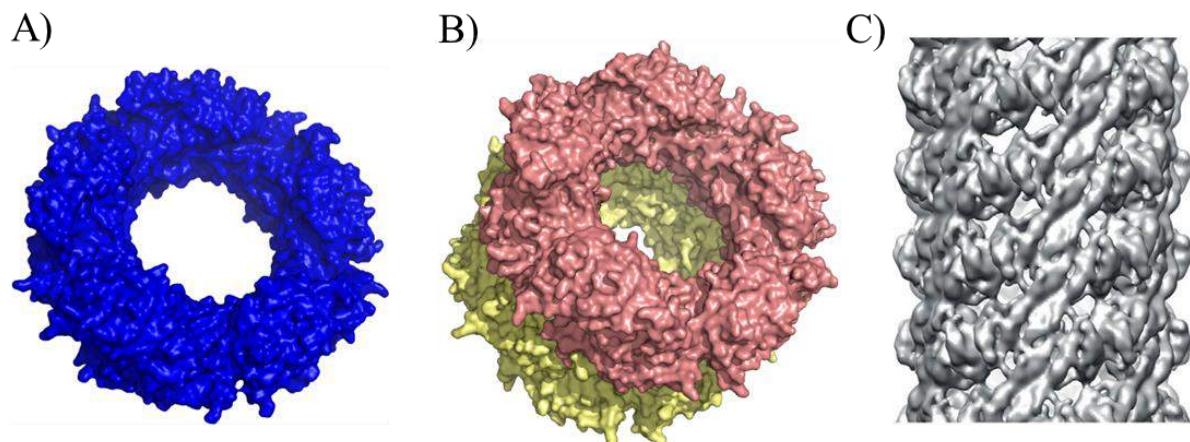

Figura 9: Estructuras de PrxI *Schistosoma mansoni* (SmPrxI) e Prx3 *Homo sapiens* (HsPrx3). (A) Estrutura decamérica de SmPrxI (código PDB 3ZTL) que apresenta atividade peroxidásica. **(B)** Estrutura de duplo decâmero na forma superoxidada (código PDB 3ZVJ). **(C)** Estrutura de alto peso molecular de HsPrx3 na forma de filamento, formada a partir da junção de decâmeros, estrutura resolvida por TEM. Imagens A e B geradas utilizando o programa PyMOL (www.pymol.org) e imagem C compilada de Radjaina e colaboradores (2015).

Com relação ao processo de superoxidação ainda é pouco investigado a capacidade de diferentes hidroperóxidos de promover esse processo. Trabalhos já apontaram que peróxidos de origem orgânica como é o caso de *t*-BOOH (*terc*-butil hidroperóxido) e CHP (hidroperóxido de cumeno) possuem uma maior capacidade de promover a superoxidação de Tpx de *E. coli* e Prx4 de rato (Baker e Poole, 2003; Ikeda *et al.*, 2011; Perkins *et al.*, 2013). Constantes cinéticas apontam que a capacidade de superoxidação pode estar relacionada a um

menor K_M sendo que Tpx de *E.coli* possui valores de K_M de 9.1 μM para CHP e 1730 μM para H_2O_2 respectivamente (Baker e Poole, 2003; Nelson *et al.*, 2013).

1.5 Peroxirredoxinas citosólicas 1 e 2 (Tsa1 e Tsa2) de *S. cerevisiae*

Em *S. cerevisiae* foram descritas cinco isoformas de peroxirredoxinas distribuídas em diversas localizações sub celulares: uma presente no núcleo celular (nTpx), uma na mitocôndria (mTpx) e três no citosol (Tsa1, Tsa2 e Ahp1) (Park e col., 2000). Das cinco Prx de *S. cerevisiae*, as formas citosólicas Tsa1 e Tsa2 pertencem à classe 2-Cys típica (subclasse Prx1-AhpC) e compartilham na sua estrutura primária 86% de identidade e 96% de similaridade, e por conta desta característica alguns autores sugerem que elas possuam funções redundantes (Chae *et al.*, 1993; Netto *et al.*, 2007; Ross *et al.*, 2000). Na figura 10 é apresentado o alinhamento das estruturas primárias de Tsa1 e Tsa2.

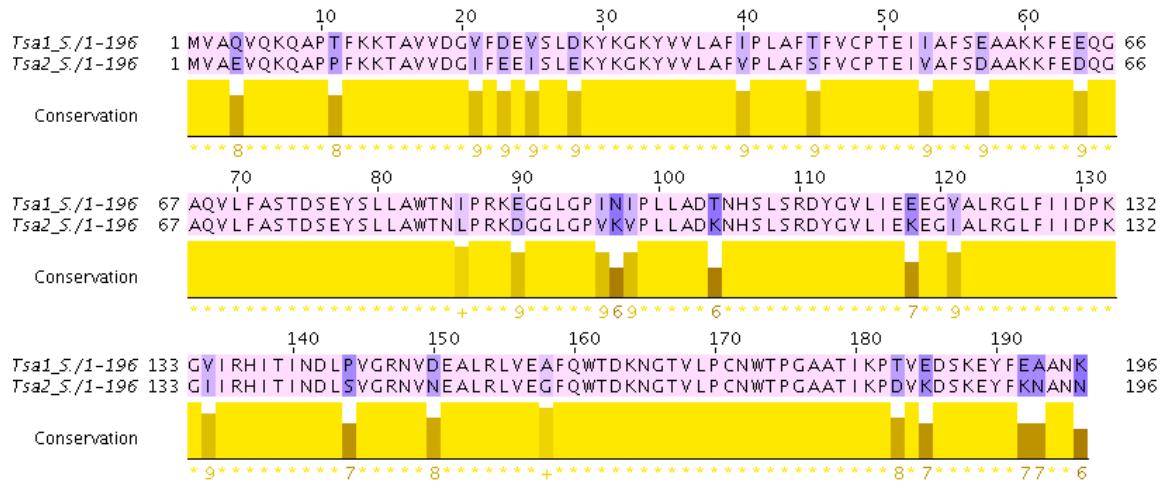

Figura 10. Análise comparativa das estruturas primárias de Tsa1 e Tsa2. Alinhamento das estruturas primárias de Tsa1 e Tsa2. Os aminoácidos idênticos estão realçados em rosa claro, enquanto que aqueles que são distintos entre as duas proteínas estão realçados em roxo. Abaixo dos alinhamentos é apresentado o índice de conservação que leva em conta as características físico-químicas dos aminoácidos alinhados. O alinhamento foi efetuado como programa Clustal Omega (www.clustal.org/) e a representação gráfica gerada pelo programa Jalview (www.jalview.org/).

Ainda que apresentem alta similaridade e identidade, existem diferenças significativas entre as mesmas no âmbito funcional. Neste contexto, as seguintes diferenças parecem bastante relevantes: **i)** Diferença de abundância intracelular: Tsa1 é uma das proteínas mais abundantes de *S. cerevisiae* contando com aproximadamente 378.000 moléculas por célula, o que representa 0.7% de todas as proteínas solúveis. Por sua vez, Tsa2 apresenta concentrações citoplasmáticas mais moderadas (~4800 cópias por célula) (Ghaemmaghami *et al.*, 2003); **ii)** Diferenças no padrão de expressão: A expressão de Tsa2 aumenta de forma significativa quando a célula é submetida a estresse oxidativo, ao contrário de Tsa1 que possui expressão

constitutiva (Kim, Kim e Rheet, 1989; Munhoz e Netto, 2004); **iii)** Diferença significativa no pK_a da cisteína envolvida na decomposição de peróxidos. Outro fato que corrobora para a suposição de não redundância entre Tsa1 e Tsa2 reside na diferença de pK_a da C_p destas proteínas. Enquanto que para Tsa1 o pK_a de C_p alcança 5.4, para Tsa2 reside em 6.3 (Ogusucu *et al.*, 2007). Cabe ressaltar que, uma vez que esta escala é logarítmica, isto significa que Tsa1 possuiria uma reatividade sobre hidroperóxidos $\sim 10 \times$ superior a de Tsa2. As razões de diferenças de pK_a entre estas proteínas muito provavelmente estão relacionados com o microambiente do sítio ativo. De forma geral, a alta reatividade da C_p está relacionada com o baixo pK_a de sua forma desprotonada ($C_p\text{-S}^-$), o qual é alcançado pelo ambiente proteico. Os tióis da maioria das proteínas possuem baixa reatividade por estarem protonados em pH fisiológico (Cys-SH), apresentando pK_a de 8.5, o mesmo da cisteína livre. No caso das Prx, a C_p está localizada próxima a um resíduo de arginina altamente conservado, o qual é um dos resíduos responsáveis pela sua desprotonação e estabilização na forma de tiolato ($C_p\text{-S}^-$) (Tairum *et al.*, 2012; Wood, Poole e Karplus, 2003). Desta forma, a diferença de reatividade de C_p entre Tsa1 e Tsa2 pode estar relacionada a aminoácidos constituintes do microambiente do sítio ativo, aspecto que será abordado a seguir.

Recentemente foi determinada por nosso grupo de pesquisa a estrutura cristalográfica de Tsa1^{C47S}, uma proteína carreando substituição da cisteína peroxidásica (C_p47) por uma serina, a qual mimetiza a forma reduzida da proteína (Tairum *et al.*, 2012) (Figura 11A). Uma vez que a forma reconhecida por Trx consiste naquela oxidada em dissulfeto, utilizamos as coordenadas de Prx1 (HBP23) de *Rattus norvegicus*, uma das poucas estruturas de Prx 2-Cys típica de eucariotos oxidada em dissulfeto determinada até o presente momento, para a construção de um modelo teórico de Tsa1 no estado oxidado (Figura 11B). O modelo obtido indica que existem grandes diferenças na topologia da proteína entre as formas oxidada e reduzida, incluindo a exposição na superfície da molécula dos dissulfetos formados entre C_p e C_R , o qual indica a face de interação com Trx.

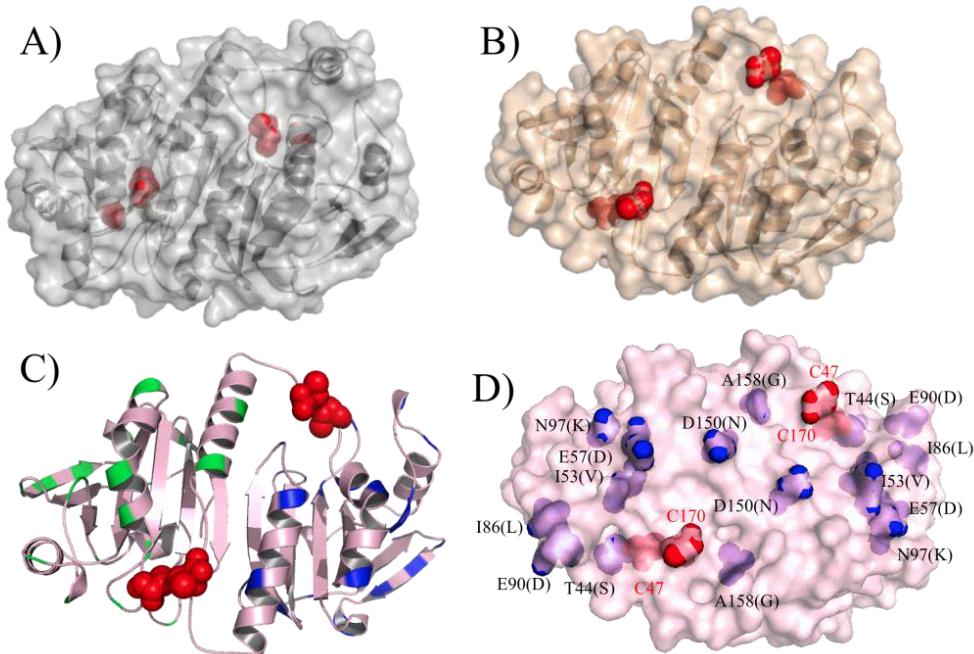

Figura 11. Análises comparativas das estruturas quaternárias de Tsa1 e Tsa2. **A)** Superfície molecular da estrutura cristalográfica de Tsa1 (dímero) de *S. cerevisiae* na forma reduzida (cinza). **B)** Superfície molecular do modelo de Tsa1 de *S. cerevisiae*, gerada utilizando o programa Modeller (salilab.org/modeller/) e as coordenadas da estrutura de *R. novergicus* (código de pdb: 1QQ2) na forma oxidada (palha). No interior das superfícies moleculares estão representadas as estruturas secundárias em *cartoon* e as cisteínas reativas estão representadas por esferas vermelhas. A transparência das superfícies moleculares foi ajustada para 40% com o intuito de tornar observáveis as representações adicionais das moléculas (*cartoon* e esferas). Em A e B a orientação das moléculas é a mesma utilizada para a geração das figuras e mudanças estruturais dependentes do estado REDOX são responsáveis pelas diferenças topológicas apresentadas. **C)** Representação em *cartoon* do modelo do dímero de Tsa1 em sua forma oxidada em dissulfeto. A estrutura é representada em rosa e as regiões da estrutura destacadas em verde e azul representam os aminoácidos que diferem entre Tsa1 de Tsa2 nos diferentes monômeros. As representações na forma de esferas em vermelho representam as cisteínas. **D)** Representação da superfície molecular do dímero de Tsa1 (rosa) evidenciando os aminoácidos de superfície (azul) que diferem de Tsa2 na superfície de contato com as Trx. A identificação dos aminoácidos supostamente envolvidos em interações diferenciais com Trx1/Trx2 é dada pelo código de uma letra (preto) e denotam os resíduos em Tsa1. Entre parênteses estão representados os AAs presentes na mesma posição espacial em Tsa2. Os aminoácidos em vermelho representam as cisteínas. Os modelos gráficos foram gerados com o auxílio do programa Pymol (www.pymol.org/).

A estrutura cristalográfica de Tsa1 também foi utilizada como referência para a análise estrutural comparativa com Tsa2. A análise dos aminoácidos diferentes de ambas as enzimas revela que 27 dos 28 aminoácidos distintos estão posicionados na superfície da enzima e alguns deles situados próximos a C_P, reforçando a hipótese de que Tsa1 e Tsa2 possam interagir de modo diferenciado com outras biomoléculas. Adicionalmente, parece de grande relevância a interação de Tsa1 e Tsa2 com tiorredoxina, uma vez que esta molécula possui papel fundamental para a transição de dímeros para estruturas HMW. A análise do modelo em dissulfeto aponta que diversos resíduos se encontram na face de interação com Trx (Figura 11C e 11D).

Levando em consideração aspectos estruturais e funcionais, um aminoácido merece destaque: T44(S) (presença de uma treonina em Tsa1 e uma serina em Tsa2. Estes

aminoácidos apresentarem características físico-químicas semelhantes, apresentam-se muito próximos a C_P e podem estar envolvidos nas diferenças no pK_a da cisteína peroxidásica e reatividade sobre substratos. Como já discutido anteriormente, Tsa1 apresenta maior afinidade por H₂O₂ do que por peróxidos orgânicos e Tsa2 não apresenta distinção de afinidade significativa entre os substratos. De fato, substituição equivalente efetuada em uma Prx de *Leishmania donovani* (T→S) resulta em considerável aumento da eficiência na decomposição de peróxido orgânico (Hofmann, Hecht e Flohé, 2002)(McHenry *et al.*, 2011; Sheinerman, Norel e Honig, 2000; Tairum *et al.*, 2012). Levando em consideração a interação de Tsa1 e Tsa2 com seu redutor biológico, a proteína Trx, ressalta-se que a levedura *S. cerevisiae* apresenta duas isoformas citosólicas de Trx, denominadas de Trx1 e Trx2, que apresentam 78% de identidade e 89% de similaridade em relação a suas estruturas primárias e apresentam quantidades de moléculas distintas por célula na fase *log* de crescimento (Trx2, 17200; Trx1, 8580) (Ghaemmaghami *et al.*, 2003). Assim como as Prx Tsa1 e Tsa2 de levedura, as Trx citosólicas de levedura são muitas vezes consideradas proteínas redundantes (Garrido e Grant, 2002). Entretanto, Oliveira e colaboradores (2010) demonstraram que a taxa de redução das Trx por TrxR1 apresentam parâmetros cinéticos levemente diferentes, sendo que Trx2 ($k_{cat}/K_M = 7.3 \times 10^7$) é mais eficientemente reduzida por TrxR1 quando comparada a Trx1 ($k_{cat}/K_M = 3.4 \times 10^7$). Adicionalmente, foi demonstrado que AA presentes na face de interação entre Trx1/Trx2 (face onde estão localizadas as cisteínas envolvidas em processos redox) e TrxR1 de levedura respondem por estas diferenças.

De forma geral, apesar dos numerosos estudos existentes com Prx e Trx de levedura, nenhuma investigação molecular detalhada sobre possíveis diferenças nas taxas de redução de Tsa1 e Tsa2 por Trx1 e Trx2 foi efetuada até o momento. Embora Tsa1 e Tsa2 apresentem somente diferenças sutis em suas estruturas, aspectos como diferenças na abundância e padrões de expressão sugerem papéis fisiológicos complementares e não redundantes. Diferenças no pK_a de C_P destas proteínas também contribuem para esta suposição, uma vez que uma maior afinidade sobre peróxidos poderia levar a uma maior superoxidação, resultando na formação de espécies de massa molecular acentuada com propriedades de chaperona molecular, que podem ter um importante papel na transdução de sinal. Neste contexto, a interação com as Trx é essencial para que em condições de alto estresse oxidativo o dissulfeto de formas diméricas de Prx seja reduzido, possibilitando a superoxidação de C_P e, consequentemente, sua organização em espécies superoxidadas de alto peso molecular. Cabe ressaltar que as estruturas tridimensionais de Tsa1, Trx1 e Trx2 já foram determinadas e

existem numerosos estudos envolvendo aspectos bioquímicos e estruturais destas proteínas. No entanto, estudos destas naturezas para Tsa2 são bastante escassos e, até o presente momento, a sua estrutura não foi determinada.

2 OBJETIVOS

Este trabalho teve como objetivos efetuar análises sistemáticas das relações moleculares de Tsa1 e Tsa2 com seus substratos redutores (Trx1 e Trx2) e seus substratos oxidantes (H_2O_2 , CHP e *t*-BOOH) com relação à atividade catalítica, susceptibilidade a superoxidação e formação de estruturas de alto peso molecular. Também foi nosso objetivo avaliar o efeito da substituição recíproca do resíduo da tríade catalítica Thr (Tsa1) e Ser (Tsa2).

3 JUSTIFICATIVA

Peroxirredoxinas 2-Cys típicas possuem alta atividade sobre peróxido de hidrogênio e hidroperóxidos orgânicos. *Saccharomyces cerevisiae* possui duas isoformas de 2-Cys Prx típicas que possuem alta identidade e similaridade e alguns autores as consideram redundantes. Por outro lado, trabalhos já demonstraram que estas proteínas possuem diferença de abundância intracelular e tem níveis de expressão aumentados quando a célula é exposta a altos níveis de hidroperóxidos. Além disso, foi demonstrado que C_P de Tsa1 apresenta um pK_a de 5.4 ao passo que Tsa2 possui um pK_a de 6.3, o que pode influenciar na reatividade destas proteínas. Diferenças nas taxas de redução de hidroperóxidos e redução do dissulfeto pelo sistema Trx podem influenciar consideravelmente o papel de proteínas tais como Tsa1 e Tsa2. Já foi demonstrado na literatura que estas proteínas estão intimamente ligadas a processos de sinalização redox, principalmente quando ocorre a inativação da proteína pela superoxidação. Tendo em vista esse contexto, análises comparativas de reatividade e superoxidação de Tsa1 e Tsa2 apresentam grande importância quando relacionadas à sinalização celular, já que hidroperóxidos muitas vezes funcionam como mediadores de sinalização. Peroxirredoxinas já foram relacionadas com inúmeros tipos de câncer e também ao processo de envelhecimento, o conhecimento aprofundado da sua bioquímica e estrutura pode contribuir significativamente para o desenvolvimento de novas terapias anticâncer e drogas específicas para combater organismos patogênicos.

4 METODOLOGIA

4.1 Reagentes

Os reagentes utilizados ao longo do trabalho como triptona, peptona, extrato de levedura, ágar, NaCl, etanol, isopropanol, ácido sulfúrico, ácido acético,, PEG, glicose, H₂O₂, brometo de etídeo, acrilamida, bisacrilamida, persulfato de amônia, NADPH, TEMED dentre outros, foram adquiridos junto a Sigma e Merk. Os demais reagentes como enzimas de restrição, marcadores de peso molecular, agarose, Taq DNA polimerase, T4 DNA ligase e oligonucleotídeos foram fornecidos pela Thermo Fischer e GE Healthcare.

Meios de Cultura para microrganismos

Para bactérias

- **2XYT:** (1.6% triptona; 1% extrato de levedura; 0.5% NaCl, 0.2% NaOH 2M).

Linhagens de Bactérias para Expressão

- ***E. coli* Tuner (DE3):** F⁻ *ompT hsdS_B(r_B⁻m_B⁻)gal dcm lacYI*(DE3).

Plasmídeo de Expressão

- pProEX/*Tsa2* (Munhoz e Netto, 2004; Oguisuco *et al.*, 2007) gentilmente cedido pelo Dr. Luis E.S. Netto (IB,USP, SP).
- pET15b/*Tsa1* (Munhoz e Netto, 2004; Netto, LES *et al.*, 1996; Oguisuco *et al.*, 2007) gentilmente cedido pelo Dr. Luis E.S. Netto (IB,USP, SP).

4.2 Preparação e transformação de bactérias eletrocompetentes

Os procedimentos para a preparação e transformação de bactérias eletrocompetentes foram realizados de acordo Ausubel e col. (1998).

4.3 Mini preparação plasmidial

A metodologia utilizada para extração de todos os plasmídeos neste estudo foi à lise alcalina, descrita Ausubel e colaboradores (1998).

4.4 Mutagênese sítio dirigida

As mutações foram efetuadas utilizando o kit *Quick Change II* (Stratagene), seguindo as orientações do fabricante. A confirmação das mutações foi efetuada por meio de sequenciamento em sequenciador automático *ABI 3730 DNA Analyser* (Thermo Fisher) após reação de sequenciamento utilizando o *kit BigDye® Terminator v3.1 Cycle Sequencing*, seguindo as orientações do fabricante (Thermo Fisher). Os oligonucleotídeos utilizados para as mutações são apresentados na tabela 1 e foram adquiridos junto a *Thermo Fisher*. O mutante $Tsa1^{T44S}$, $Tsa1^{T44A}$, $Tsa1^{\Delta CT}$ estavam disponíveis, pois são provenientes de outro estudo realizado paralelamente (Resultados em Apêndice A). Para a realização das mutações sítio dirigidas de simples troca de aminoácidos foram utilizados os oligonucleotideos apresentados na tabela a seguir.

Tabela 1. Oligonucleotídeos utilizados para a produção dos mutantes de *Tsa2*.

Oligonucleotídeos	Sequencia
Mutagênicos	
Tsa2^{S44T}F	5' ATTGGCTTT ACT TTTGTC TG TC 3'
Tsa2^{S44T}R	5' GACAGACAAA AGT AAAAGCCAAT 3'
Tsa2^{C47S}F	5' TTCATTGTC AGT CCAACTGAGA 3'
Tsa2^{C47S}R	5' TCTCAGTTGG ACT GACAAATGAA 3'
Oligonucleotídeos	
T7 Forward	5' ATTTAGGTGACACTATAG 3'
T7 Reverse	5' TGCTAGTTATTGCTCAGGC GG 3'

4.5 Expressão de proteínas em linhagens de bactérias

Linhagens de *E. coli* Tuner (DE3) contendo os plasmídeos de expressão foram cultivadas em 2 mL de meio 2XYT/Amp a 37 °C/16 hs/250 rpm em agitador orbital. Em

seguida, toda a cultura foi transferida para 0.5 L de meio 2XYT e cultivada até $OD_{600} = 0.6$. Nesse estágio, foi adicionado IPTG a concentração final de 0.5 mM. A indução foi realizada 30 °C/16 hs/250 rpm em agitador orbital, após esse período o cultivo foi centrifugado a 4° C/20 min/5000 rpm e as células foram ressuspensas em tampão Tris 10 mM, pH 8.0, e condicionadas em ultrafriezzer (-80.°C) até o momento do uso. As células foram rompidas por 3 ciclos de sonicação (30 s sonicando, 60 s descansando) com 35% de amplitude e foram tratadas com sulfato de estreptomicina para a remoção dos ácidos nucléicos ([] final = 1%). Posteriormente ocorreu uma nova centrifugação de 45 min/4 °C/12000 rpm, o precipitado foi descartado e foram coletados somente os extratos celulares livres de ácidos nucléicos. As proteínas contendo cauda de histidina (inseridas pelo plasmídeo de expressão) foram purificadas por cromatografia de afinidade em colunas Hi-Trap 5 mL (GE Healthcare) em gradiente de imidazol.

Para as proteínas Trx1 e Trx2 expressas utilizando plasmídeos pET17b foi realizada purificação através de fervura (*boiling method*), descrito por Porqué e colaboradores (1977). Quando necessário estas proteínas foram submetidas uma segunda etapa de purificação através de cromatografia de exclusão molecular em coluna Hitrap 16/600 Superdex 200 em ÄktaPrime (GE Healthcare).

4.6 Quantificação de proteínas

Após a purificação as proteínas foram submetidas à cromatografia de exclusão molecular para retirada do imidazol utilizado na purificação utilizando a coluna PD10 (GE Healthcare) e foram quantificadas pelo coeficiente de extinção molar, que pode ser acessado no seguinte endereço eletrônico: <http://www.expasy.org/tools/protparam>. Tsa1: 24075 M⁻¹.cm⁻¹ (oxidada) e 23950 M⁻¹.cm⁻¹ (reduzida); Tsa1^{T44S}: 24075 M⁻¹.cm⁻¹ (oxidada) e 23950 M⁻¹.cm⁻¹ (reduzida); Tsa2: 27055 M⁻¹.cm⁻¹ (oxidada) e 26930 M⁻¹.cm⁻¹ (reduzida); Tsa2^{S44T}: 27055 M⁻¹.cm⁻¹ (oxidada) e 26930 M⁻¹.cm⁻¹ (reduzida); TrxR1: 27640M⁻¹.cm⁻¹ (oxidada) e 27390 M⁻¹.cm⁻¹ (reduzida); Trx1: 10095 M⁻¹.cm⁻¹ (oxidada) e 9970 M⁻¹.cm⁻¹ (reduzida); Trx2: 11585 M⁻¹.cm⁻¹ (oxidada) e 11460 M⁻¹.cm⁻¹ (reduzida).

4.7 Clivagem das caldas de poli Histidina (His-Tag)

A retirada da His-Tag quando necessária foi realizada utilizando 3C protease. Para tanto as proteínas após a purificação por IMAC, foram submetidas a uma gel filtração

utilizando coluna PD10 (GE Healthcare) e mantidas em tampão Tris 10 mM, pH=8.0. Foram adicionados as amostras 0.01 equivalentes moleres de 3C protease e a reação foi mantida a 4° C durante 16 horas. Após a reação de clivagem foi realizada uma nova etapa de cromatografia de afinidade a metal em colunas Hi-Trap 5mL, para retirada da His-Tag e da 3C protease.

4.8 Determinação das constantes cinéticas

As constantes cinéticas foram determinadas através do ensaio de consumo do NADPH ($\epsilon_{340\text{nm}} = 6200 \text{ M}^{-1} \text{ cm}^{-1}$) pelo sistema tiorredoxina conforme Cha e col. (1994). A reação foi realizada a 30 °C com volume final de 100 µl contendo NADPH a 150 µM, concentrações variáveis de hidroperóxidos, 1 µM de Prx, 2 µM Trx1 ou Trx2 e 0.3 µM de TrxR1, em tampão Hepes 50 mM pH 7.0 contendo 100 µM de DTPA e 1 mM de azida. Todos os reagentes exceto NADPH e o hidroperóxido foram misturados e mantidos a 30 °C por pelo menos 3 minutos para termoestabilização. Após esse período foi adicionado o NADPH e foram iniciadas as medidas de absorbância, após um período de estabilização da medida de 30 segundos foi adicionado o hidroperóxido. O tempo de medida total foi de 3 minutos sendo que a absorbância foi medida a cada 2 segundos. A determinação das constantes cinéticas foi determinada através da equação de cinética do estágio estacionário variando-se somente a concentração do hidroperóxido ou a concentração de Trx, para realização dos cálculos e construção dos gráficos foi utilizado o programa GraphPad Prism.

4.9 Análise de inativação de Tsa1 e Tsa2 pelo substrato

A análise de inativação pelo substrato oxidante de Tsa1 e Tsa2 foi realizada utilizando ensaio de consumo do NADPH pelo sistema tiorredoxina. Foi monitorado o decaimento da absorbância ($\epsilon_{340\text{nm}} = 6200 \text{ M}^{-1} \text{ cm}^{-1}$) conforme descrito Chae e colegas (1994). A reação foi realizada a 30 °C com volume final de 100 µl contendo NADPH a 150 µM, concentrações variáveis de hidroperóxidos, 1 µM de Tsa1 ou Tsa2, 2 µM Trx1 ou Trx2 e 0.3 µM de TrxR1, em tampão Hepes 50 mM pH 7.0 contendo 100 µM de DTPA e 1 mM de azida. O experimento foi realizado conforme descrito acima no item 4.8, somente diferindo pelo tempo de leitura que foi de 6 minutos. A construção dos gráficos foi realizada utilizando o programa GraphPad Prism.

4.10 Análise de inativação por superoxidação utilizando SDS-PAGE em condições não redutoras

A análise de inativação por superoxidação foi realizada utilizando o sistema tiorredoxina. A reação foi realizada a 30 °C por 15 minutos em volume final de 50 µl contendo NADPH a 150 µM, concentrações variáveis de hidroperóxidos (0.01 – 10 mM), 9.3 µM de Prx, 1 µM Trx1 ou Trx2 e 0.3 µM de TrxR1, em tampão Hepes 50 mM pH 7.0 contendo 100 µM de DTPA e 1 mM de azida. Após, decorrido o tempo de reação, foi adicionado 100 mM de NEM a reação para promover a alquilação das cisteínas livres e evitar artefatos na detecção em gel. Para verificar o aparecimento de formas superoxidadas as amostras foram submetidas à SDS-PAGE sem a presença de redutores e a relação monômero/dímero foi analisada.

4.11 Obtenção de Tsa1 superoxidada

Para a obtenção da proteína Tsa1 superoxidada foi realizado um ensaio utilizando sistema Trx, contendo TrxR1 sem His-Tag. A reação foi realizada a 30 °C com volume final de 15 mL contendo NADPH a 150 µM, 10 mM de CHP, 9.3 µM de Prx, 1 µM Trx1 e 0.3 µM de TrxR1, em tampão Hepes 50 mM pH 7.0, 100 µM de DTPA e 1 mM de azida. Após decorrido 30 minutos de reação Tsa1 superoxidada foi purificadas por cromatografia de afinidade a metal em colunas Hi-Trap 1mL (GE Healthcare) em gradiente de imidazol. Como somente Tsa1 possuía His-Tag foi possível separá-la das outras proteínas e componentes da reação. Após a purificação a proteína foi submetida à cromatografia de exclusão molecular para retirada do imidazol utilizado na purificação e foi quantificada pelo coeficiente de extinção molar.

4.12 Determinação da taxa de superoxidação utilizando fluorescência intrínseca do triptofano

Tsa1 e Tsa2 foram reduzidos por 20 mM de DTT por 1 hora, o qual foi depois removido por dois procedimentos de gel filtração utilizando colunas PD10 (GE Healthcare). A eficiência da redução foi avaliada com o auxílio de DTNB acompanhando a formação de TNB ($\lambda=412$ nm) em tampão denaturante, e foi calculada a quantidade de cisteínas livres, sendo considerados aceitáveis valores acima de 90%. As enzimas em tampão 40 mM fosfato de sódio (pH 7.4) foram rapidamente misturadas com concentrações crescentes de H₂O₂ ou CHP a 30 °C em espectrofluorímetro *Applied*

Photophysics SX 17MV acoplado a *stopped flow* com tempo de mistura menor que 2 ms. Os comprimentos de onda utilizados foram 280 nm para excitação e 340 nm para emissão. A constante de superoxidação de Tsa1 por H₂O₂ e CHP calculada através do retorno da fluorescência intrínseca do triptofano após a reação com o hidroperóxido.

4.13 Cristalização de proteínas

Após a purificação de Tsa2 e do mutante Tsa2^{C47S} foram realizados ensaios iniciais de crescimento de cristais utilizando a infraestrutura do Laboratório Nacional de Luz Síncrotron (Campinas/Brasil) e do Centro de Investigaciones Biológicas (Madrid/Espanha). Foram realizadas triagens utilizando os kits Crystal Screen 1 e 2 (Hampton Research-96 condições), Matrix Maker (Emerald Biosystems) e Honeybee 963 (Genome Solutions), PACT, JCSG (Nextal/Qiagen-96 condições cada), SaltRx (Hampton Research-96 condições) e Precipitant Synergy (64 condições) – Emerald BioSystems. Foram realizados experimentos variando-se a concentração de proteínas (5, 7, 10 mg/mL) em tampão Tris-HCl 5 mM previamente tratadas com DTT (10 mM) ou H₂O₂ (1 mM). Condições iniciais de cristalização foram refinadas quanto a precipitantes, sais e pH. Além disso, foram abordados também procedimentos de semeadura de cristal e triagem de aditivos e detergentes.

4.14 Cromatografia de exclusão molecular (SEC)

O estado de oligomérico das proteínas e formação de HMW foi analisado por HPLC analítico utilizando sistema Jasco série vp. equipado com bomba PU 2880 Plus, forno de coluna CO 2065, detector PDA MD 2018 e detectores de fluorescência FP 2020 Plus. Foram utilizadas colunas *Phenomenex BioSep-SEC-S3000* (7,8 × 300 mm, 5 cm, faixa de separação 5 a 700 kDa), equilibradas com Tris-Cl 100 mM pH 7.4 contendo 100 mM de NaCl. A eluição dos componentes foi monitorada por UV ($\lambda = 280$ nm) e por fluorescência ($\lambda_{\text{ex}}=280$ e $\lambda_{\text{em}}=330$ nm). Os padrões de massa molecular a serem usados foram: tiroglobulina (bovina) (670 kDa), γ -globulina (bovina) (158 kDa), ovalbumina (frango) (44 kDa), mioglobina (cavalo) (17 kDa) e Vitamina B₁₂ (14.2 kDa).

4.15 Espalhamento dinâmico de luz (DLS)

As medidas de espalhamento dinâmico de luz (DLS) de proteínas envolvidas neste projeto foram realizadas no Laboratório de Genética e Biologia Molecular, Antioxidantes e

Radicais Livres (IB-USP) utilizando o equipamento *DYNAPRO* (Protein Solutions). Para análises da estrutura das proteínas foram realizados ensaios com as proteínas reduzidas (5 mM de TCEP) ou oxidadas (1.2 equivalentes de H₂O₂). Para análise da formação de complexos HMW amostras de proteínas foram submetidas a ensaios de oxidação do NADPH utilizando altas concentrações de hidroperóxidos. A reação foi realizada a 4 °C *overnight* em volume final de 100 µL contendo NADPH a 600 µM, hidroperóxido (10 mM), 1 mg/mL (42.6 µM) de Prx, 1 µM Trx1 e 0.3 µM de TrxR1, em tampão Hepes 50 mM pH 7.0 contendo 100 µM de DTPA e 1 mM de azida. Antes dos experimentos todas as amostras foram centrifugadas a 14.000 g por 15 minutos para a decantação de proteínas desnaturadas e filtradas em microfiltros Millex® 0.22µm (Millipore). As medidas foram realizadas em volume final amostra de 20 µL com intensidade do laser ajustada para 100% (880 nm). Para cada amostra foram efetuadas 200 leituras (10 subleituras/leitura) a 20°C e foi utilizado o modelo de esferas para o cálculo do raio de giro.

4.16 Avaliação da estrutura em meio líquido pelo método de espalhamento de luz em baixo ângulo (SAXS)

Amostras em tampão 10 mM Tris-HCl pH 8 foram centrifugadas por 10 min/ 14.000 rpm/ 4 °C e em seguida, filtradas para remoção de agregados. Os dados de SAXS foram coletados na linha de luz Linha B21 do *Diamond Light Souce* (Oxfordshire, Inglaterra). O λ utilizado foi de 1.48 Å e a distância inicial do detector *Pilatus* (Dectris) utilizado para registrar os padrões de dispersão foi de 165 milímetros. Linhas de base tampão foram coletadas em condições idênticas para garantir uma correção do solvente precisa. O cálculo da P_r e D_{max} foi realizado utilizando o programa PRIMUSqt (Konarev *et al.*, 2003), modelos foram gerados utilizando o programa DAMMIF (Franke e Svergun, 2009) e as coordenadas cristalográficas foram sobrepostas utilizando o programa Supcomb (Kozin e Svergun, 2001a).

4.17 Análise de formação de estruturas de alto peso molecular (HMW) de Tsa1 e Tsa2 por microscopia eletrônica de transmissão (TEM)

Análise da formação de complexos HMW foi por realizada por TEM utilizando amostras de Prx após a reação com sistema Trx utilizando CHP como substrato, metodologia apresentada no item 4.10. Amostras foram centrifugadas por 30 min/14000 rpm/4 °C e filtradas microfiltros Millex® 0.22 µm (Millipore), diluídas em tampão Hepes 50 mM pH 7.4

quando necessário. Grades de cobre Ultrathin Carbon Film / Holey Carbon 400 mesh/ (TE Pella) foram carregadas negativamente a 15 mA por 25 seg em aparelho Easy Glow (Ted Pella). Para obtenção de imagens de boa qualidade as amostras foram diluídas quando necessário. Um volume de 3 μL de amostra foi aplicado sobre a grade, após 3 min o excesso de líquido foi removido com auxílio de papel filtro. Para a retirada do sal presente da amostra foram adicionados 3 μl de água sobre a grade sendo esta seca com papel filtro, este processo foi repetido por 3 vezes. Posteriormente foram aplicados 3 μL de acetato de uranila 2%, após 30 seg seu excesso foi removido com papel filtro, este processo foi realizado 2 vezes. A grade então foi seca a temperatura ambiente e acondicionada a temperatura ambiente. As imagens de TEM foram adquiridas 1-3 μM de foco, 15-18000 \times de magnificação utilizando microscópio eletrônico de transmissão Jeol JEM-2100 operado a 200 kV e equipado com câmera F-416 CMOS (Tietz Video and Image Processing Systems).

5 RESULTADOS

Para facilitar o entendimento desta tese os resultados serão apresentados em cinco capítulos. No **Capítulo 1** são demonstrados dados referentes à reatividade de Tsa1 e Tsa2 sobre seus substratos oxidantes H_2O_2 , *t*-BOOH e CHP e sobre seus substratos redutores Trx1 e Trx2. O **Capítulo 2** demonstrara resultados referentes à superoxidação da C_P de Tsa1 e Tsa2, influenciada por diferentes hidroperóxidos e são caracterizados mutantes de aminoácidos que influenciam a resposta diferencial destas proteínas a este processo. No **Capítulo 3** são demonstrados resultados referentes a influencia da superoxidação na formação de estruturas de alto peso molecular de Tsa1 e Tsa2. O **Capítulo 4** demonstra resultados de cristalização de Tsa2 e um modelo estrutural obtido através de espalhamento de raio X de baixo ângulo (SAXS) . O **Capítulo 5** resume o artigo apresentado no Apêndice A onde é demonstrada a importância da Th44 na atividade e manutenção da estrutura de Tsa1 e também algumas abordagens adicionais referentes ao mecanismo de catálise das Prx.

5.1 CAPÍTULO 1 - Reatividade e superoxidação de Tsa1 e Tsa2

5.1.1 Determinação de constantes cinéticas de Tsa1 e Tsa2 sobre substratos oxidantes

As proteínas Tsa1 e Tsa2 possuem alta reatividade sobre H₂O₂ e peróxidos orgânicos e podem ser eficientemente reduzidas por Trx1 e Trx2 (Ogusucu *et al.*, 2007; Watzlawik *et al.*, 2006). Com o objetivo de verificar diferenças nas taxas de redução de Tsa1 e Tsa2 sobre hidroperóxidos foi utilizado o ensaio de NADPH. Os parâmetros cinéticos foram calculados utilizando a equação de estado estacionário, variando somente a concentração do hidroperóxido e mantendo a concentração de Trx fixa ou variando-se a concentração de Trx e mantendo fixa a concentração de hidroperóxido. Na determinação das constantes cinéticas de redução de hidroperóxidos foram utilizadas concentrações saturantes de Trx (2 μM) de modo que o passo de redução da Prx não fosse um limitante para a reação. Nos ensaios onde foi variado o substrato redutor (Trx) foi utilizada uma concentração saturante de H₂O₂ de modo que o passo oxidação da Prx também não fosse um limitante da reação.

As taxas de redução de Tsa1 e Tsa2 sobre seus substratos oxidantes foram determinadas utilizando concentrações crescentes de H₂O₂, CHP e *t*-BOOH e concentração fixa de Trx1 e de Trx2. Nestes experimentos foram utilizadas concentrações saturantes de Trx (2μM), concentração na qual o passo de redução da Prx não é limitante.

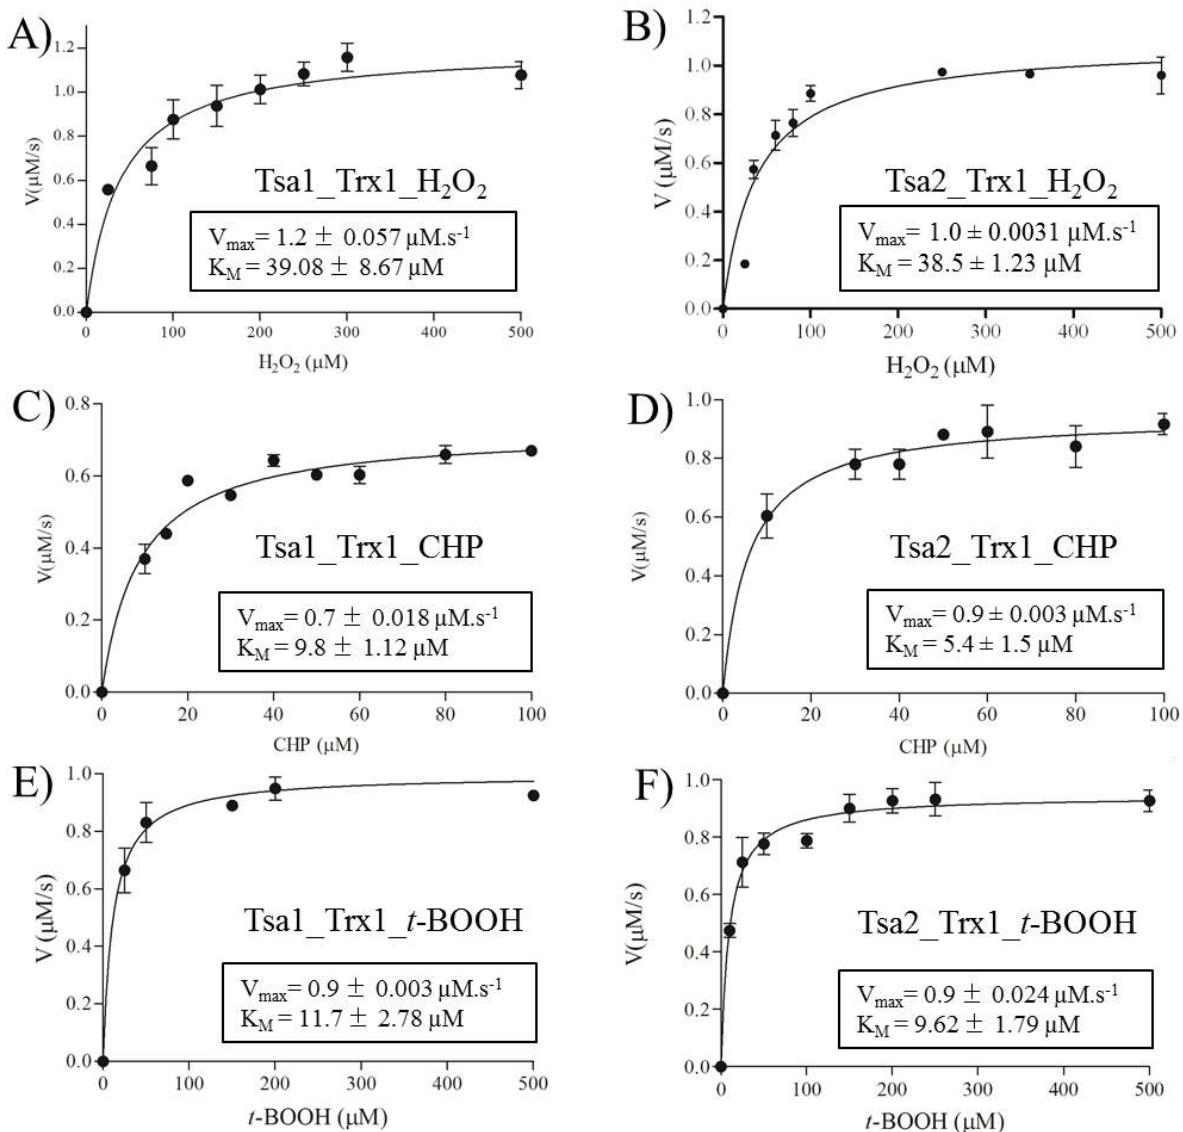

Figura 12. Efeito da concentração de hidroperóxidos na atividade peroxidásica de Tsa1 e Tsa2 ligada a oxidação de NADPH via Trx1 e TrxR1. A oxidação do NADPH foi monitorada a 30 °C pela diminuição da absorbância a 340 nm. A reação (100 µl) foi realizada em tampão 50 mM Hepes-NaOH pH 7.4 contendo 1 mM de azida, 100 µM de DTPA na presença de 150 µM de NADPH, 1 µM de Tsa1 ou Tsa2, 2 µM de Trx1, 0.3 µM de TrxR1 e diferentes concentrações de hidroperóxidos. A reação foi iniciada pela adição do hidroperóxido. As curvas representam a velocidade de oxidação do NADPH em diferentes concentrações de H₂O₂, CHP e t-BOOH.

Utilizando Trx1 como substrato redutor foram obtidos parâmetros cinéticos semelhantes entre Tsa1 e Tsa2 quando o substrato utilizado foi o H₂O₂ e uma variação maior foi verificada quando foi utilizado como substrato CHP e t-BOOH (Figura 12). Os valores de V_{max} de Tsa1 foram 1.2 µM.s⁻¹ para H₂O₂, 0.7 µM.s⁻¹ para CHP e 0.9 µM.s⁻¹ para t-BOOH, os valores de K_M foram de 39.08 µM para H₂O₂, 9.8 µM para CHP e 11.7 µM para t-BOOH. Em conjunto os resultados indicam uma maior afinidade de Tsa1 por peróxidos orgânicos, resultado similar foi observado para Tsa2. Para hidroperóxidos orgânicos foi observada uma diminuição significativa do K_M tanto para CHP (5.4 µM) quanto para t-BOOH (9.62 µM).

quando comparado com H_2O_2 ($38.5 \mu\text{M}$) (Figura 12, Tabela 2). Entretanto, enquanto a eficiência catalítica para todas as condições testadas foi na ordem de $\sim 10^4 \text{ M}^{-1}\text{s}^{-1}$, chama a atenção que para Tsa2 quando foi utilizado CHP foi determinado $\sim 10^5 \text{ M}^{-1}\text{s}^{-1}$, indicando que este é um substrato oxidante melhor para Tsa2. Quando o substrato redutor foi Trx2 assim como o observado para Trx1, apenas diferenças sutis foram verificadas nas taxas de redução (Figura 13). Novamente, a eficiência se mostrou mais acentuada para CHP (Figura 12, Tabela 2).

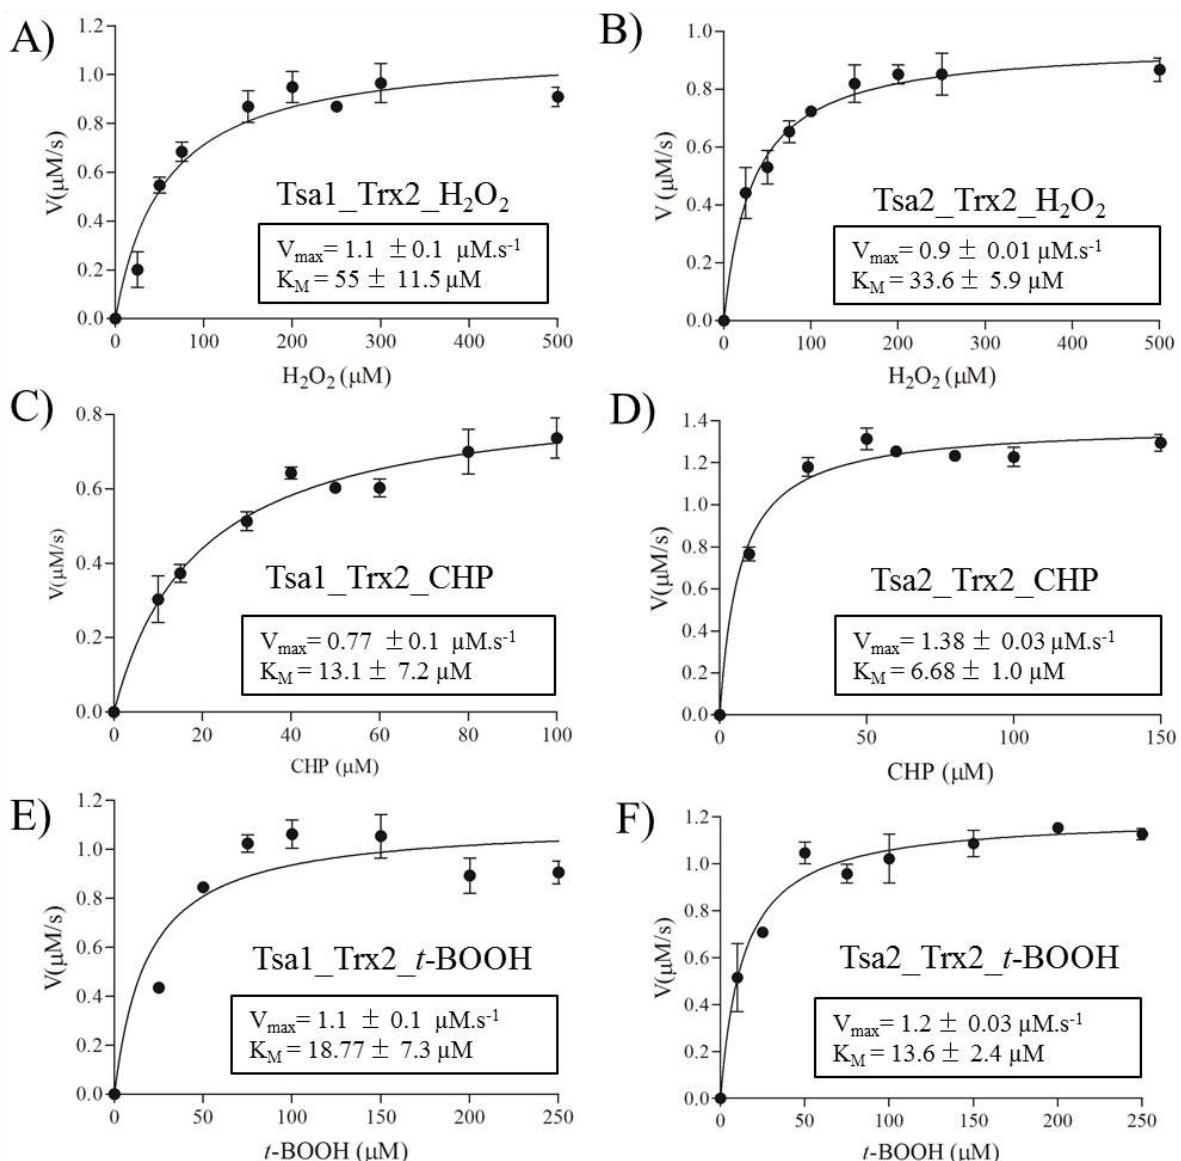

Figura 13. Efeito da concentração de diferentes hidroperóxidos na atividade peroxidásica de Tsa1 e Tsa2 utilizando Trx2. A oxidação do NADPH foi monitorada a 30°C pela diminuição da absorbância a 340 nm . A reação ($100 \mu\text{l}$) foi realizada em tampão 50 mM Hepes-NaOH pH 7.4 contendo 1 mM de azida, $100 \mu\text{M}$ de DTPA na presença de $150 \mu\text{M}$ de NADPH, $1 \mu\text{M}$ de Tsa1 ou Tsa2, $2 \mu\text{M}$ de Trx2, $0.3 \mu\text{M}$ de TrxR1 e diferentes concentrações de hidroperóxidos. A reação foi iniciada pela adição do hidroperóxido. As curvas representam a velocidade de oxidação do NADPH em diferentes concentrações de H_2O_2 , CHP e *t*-BOOH.

Cabe ressaltar que as constantes de Tsa1 e Tsa2 para decomposição de H₂O₂ ou peróxidos orgânicos obtidas são inferiores as determinadas metodologias que não envolvem reações intermediárias de troca de elétrons entre as proteínas do sistema Trx envolvendo diversas reações de oxido redução (Figura 4). De fato, através de ensaio de competição com HRP foram determinadas constantes na ordem $\sim 10^7 \text{ M}^{-1} \cdot \text{s}^{-1}$ (Ogusucu *et al.*, 2007; Tairum *et al.*, 2012; Toledo *et al.*, 2011), similar ao determinado para outras Prx. As constantes de redução de Trx1 e Trx2 por TrxR1 revelaram constantes de $10^7 \text{ M}^{-1} \text{s}^{-1}$ (Oliveira *et al.*, 2010).

Estes resultados sugerem reações intermediárias lentas, seja a formação de dissulfeto de Tsa1/Tsa2 ou sua redução por Trx. Estas etapas devem limitar as constantes de decomposição de hidroperóxido no ensaio acoplado utilizando o sistema Trx. Corroborando para esta hipótese, demonstramos por meio de ensaios fluorométricos que a constante de pseudo-primeira ordem de Tsa1 e Tsa2 para redução de H₂O₂ e CHP reside na ordem de $10^7 \text{ M}^{-1} \text{s}^{-1}$ (Apêndice A- Manuscrito em fase final de elaboração que será submetido ao periódico *Nature chemical biology*). Para avaliar as taxas de redução de Tsa1 e Tsa2 foram empregadas análises cinéticas que serão apresentadas nas próximas seções.

5.1.2 Determinação de constantes cinéticas de Tsa1 e Tsa2 utilizando Trx1 ou Trx2

Para determinar as constantes de reação de Tsa1 e Tsa2 com Trx1 e Trx2 foram realizados experimentos variando-se a concentração de Trx e utilizando H₂O₂ como substrato oxidante em altas concentrações (500 μM) de forma que a reação da Prx com o hidroperóxido não se apresenta como um passo limitante da reação (Figura 14). Foram realizados experimentos somente com H₂O₂, pois a utilização em altas concentrações de CHP e *t*-BOOH causa inibição da reação, tema este que será abordado no próximo capítulo.

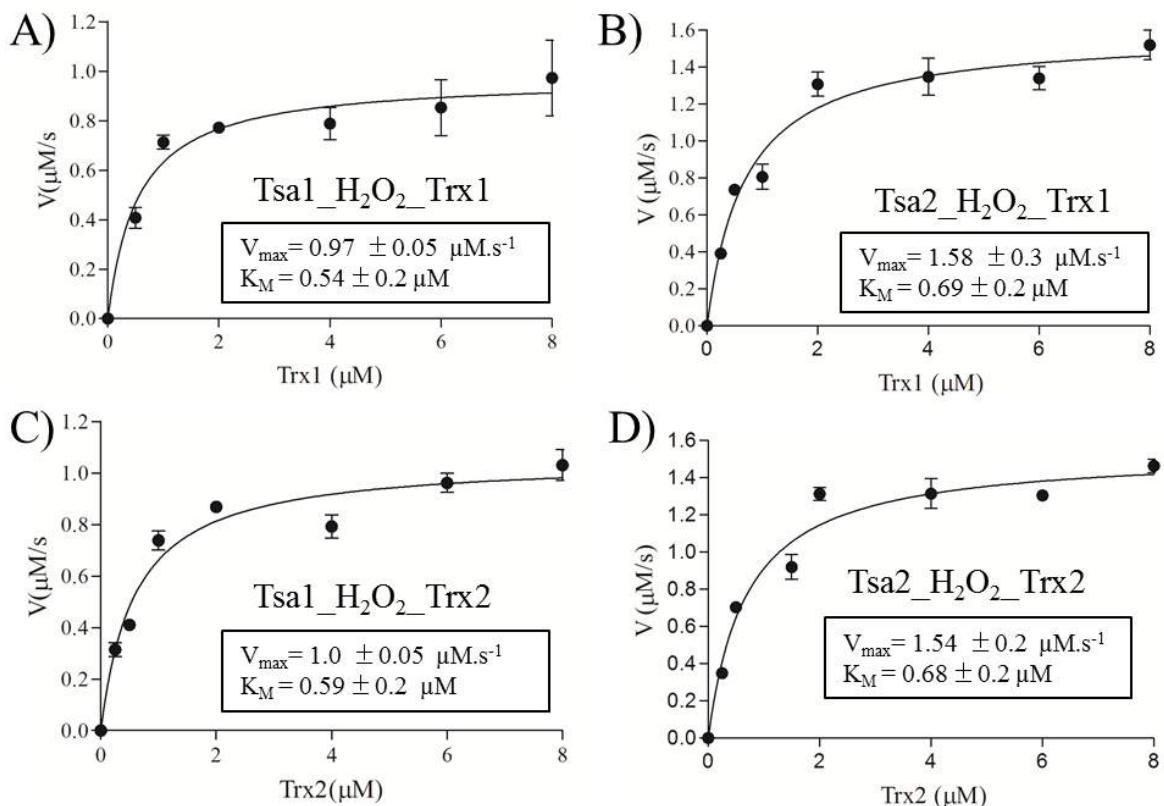

Figura 14. Efeito da concentração de tiorredoxina na atividade peroxidásica de Tsa1 e Tsa2 ligada a oxidação de NADPH via H_2O_2 e TrxR1. A oxidação do NADPH foi monitorada a 30 °C pela diminuição da absorbância a 340 nm. A reação (100 μl) foi realizada em tampão 50 mM Hepes-NaOH pH 7.4 contendo 1 mM de azida, 100 μl de DTPA na presença de 150 μM de NADPH, 1 μM de Tsa1 ou Tsa2, 0,3 μM de TrxR1, 500 μM de H_2O_2 e diferentes concentrações de tiorredoxina. A reação foi iniciada pela adição do hidroperóxido. As curvas representam a velocidade de oxidação do NADPH em diferentes concentrações de Trx1 e Trx2.

Experimentos para determinação das constantes de Tsa1 e Tsa2 com seus substratos redutores Trx1 e Trx2 revelaram resultados contrastantes. Enquanto que para Tsa1 ambas as Trx apresentam resultados muito semelhantes ($V_{max,\text{Trx1}} = 0.97$ e $V_{max,\text{Trx2}} = 1.0 \mu\text{M}/\text{s}$; $K_{M,\text{Trx1}} = 0.54$ e $K_{M,\text{Trx2}} = 0.59$) Tsa2 apresentou parâmetros superiores ($V_{max,\text{Trx1}} = 1.58$ e $V_{max,\text{Trx2}} = 1.54 \mu\text{M}/\text{s}$; $K_{M,\text{Trx1}} = 0.69$ e $K_{M,\text{Trx2}} = 0.68 \mu\text{M}/\text{s}$). Neste contexto enquanto a eficiência catalítica para Tsa1 foi de $\sim 6 \times 10^5 \text{ M}^{-1}\text{s}^{-1}$ utilizando Trx1 e Trx2, para Tsa2 as constantes foram de $\sim 2 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$, ou seja uma diferença significativa nas taxas de redução. Os resultados podem sugerir duas possibilidades não excludentes: 1) Uma menor eficiência de redução de Tsa1 por Trx1 ou Trx2 ou 2) uma vez que as enzimas são passíveis de superoxidação de C_P estes resultados poderiam indicar que C_P de Tsa1 é mais suscetível superoxidação o que mascararia as taxas de redução em razão de que uma parcela das proteínas presentes na reação serem superoxidadas a cada ciclo de redução. Os resultados dos experimentos de cinética com sistema Trx são apresentados de maneira comparativa na tabela 2.

5.1.3 Determinação das constantes de redução de Tsa1 e Tsa2 por Trx1 utilizando fluorescência intrínseca do triptofano

Visando aprofundar no entendimento das relações de Tsa1/Tsa2 e Trx1/Trx2 foram realizadas abordagens da redução acompanhando alterações da fluorescência intrínseca de resíduos de Trp. Este trabalho contou com a participação do aluno Felipe Zurlo (Ciências Biológicas – Unesp/CLP), sendo tema do seu trabalho de conclusão de curso.

Inicialmente, foram realizadas varreduras de fluorescência para se verificar alterações de fluorescência entre os estados reduzidos e oxidados de Tsa1/Tsa2 e Trx1/Trx2. Os resultados revelaram que Tsa1 e Tsa2 possuem diferença significativa na emissão de fluorescência do Trp no estado reduzido e oxidado (Figuras 15A e 15B). Por outro lado a avaliação da fluorescência de Trx1 revelou que apesar de possuir um resíduo de Trp (resíduo 29) próximo aos resíduos de Cys do sítio ativo (30 e 33) não foi detectada diferenças no perfil de fluorescência da proteína (Figura 15C). No caso de Trx2 foi possível detectar que existe um pequeno aumento da fluorescência quando a enzima está no estado reduzido, no entanto a diferença é ínfima e pode ser desconsiderada (Figura 15D).

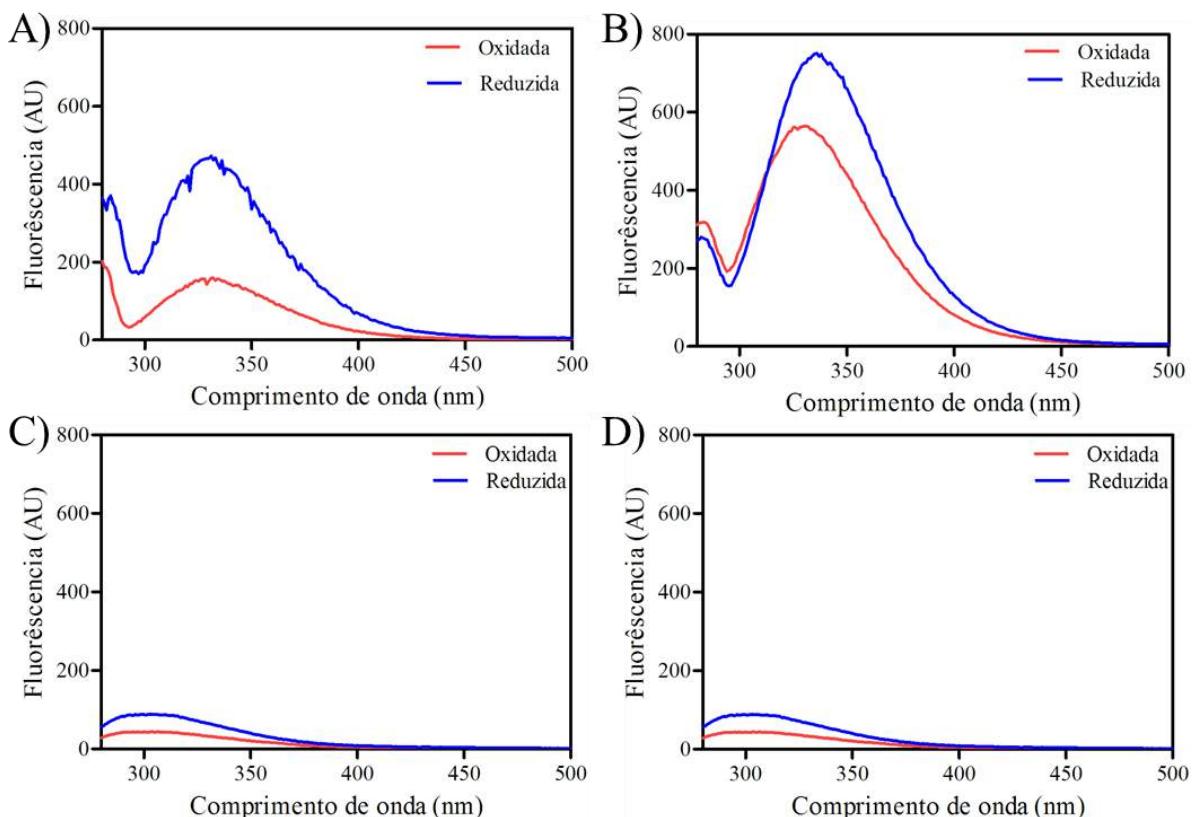

Figura 15. Diferença da fluorescência de Tsa1, Tsa2, Trx1 e Trx2. Amostras das proteínas Tsa1 (A), Tsa2 (B), Trx1 (C) e Trx2 (D) foram previamente reduzidas com DTT (10 mM) ou oxidadas (1.2 equivalentes de H₂O₂) e a emissão de fluorescência foi monitorada (280 a 500 nm) após excitação a 280 nm. Linha vermelha representa a proteína reduzida e a linha azul oxidada.

Apesar de ser curiosa a fluorescência ínfima ou inexistente das Trx de levedura, este fenômeno já é conhecido para outras proteínas e pode ser explicado por fatores como ligações específicas, solvente e fatores ambientais (Cowgill e Lang, 1970). Neste contexto, os resultados revelam que é possível determinar as taxas de redução de Tsa1 e Tsa2 acompanhando o aumento da fluorescência no processo de redução por Trx1/Trx2.

Os experimentos para estimar as taxas de redução de Tsa1 e Tsa2 pela Trx1 foram realizados no laboratório de Bioquímica e Radicais Livres coordenado pela Profa. Dra. Ohara Augusto (IQ/USP) utilizando espectrofluorímetro com *stopped-flow*. Para a determinação das taxas de redução, Tsa1 e Tsa2 foram previamente oxidadas com 1.2 equivalentes de H₂O₂ e foram misturadas a Trx1 previamente reduzida com 20 mM de DTT e o aumento da fluorescência foi monitorado (excitação a 280nm e emissão 340nm) (Figura 16). Para a determinação das constantes de pseudo-primeira ordem foi utilizado uma concentração molar 8 × maior de Trx1 para Tsa1 e Tsa2 (8 : 1 μM). Através dos experimentos a constante pseudo-primeira ordem da redução de Tsa1 por Trx1 foi determinada como $1.8 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$ e a constante de redução de Tsa2 por Trx1 como $4.0 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$. Os dados obtidos nestes ensaios apresentam-se semelhantes aos obtidos utilizando o ensaio de NADPH, onde se obteve uma constante de redução por Trx1 de $5.67 \times 10^5 \text{ M}^{-1}\text{s}^{-1}$ para Tsa1 e $2.2 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$ para Tsa2. Neste contexto os dados revelam que a redução de Tsa1 e Tsa2 ocorre de forma extremamente eficiente.

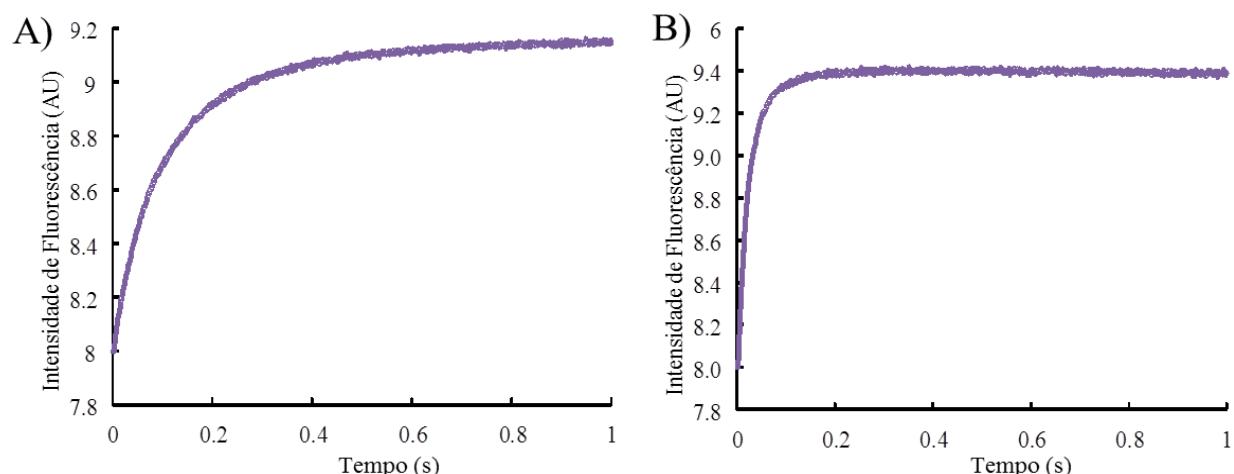

Figura 16. Mudança de fluorescência de Tsa1 e Tsa2 pela adição concentrações crescentes de Trx1 reduzida. Tsa1 (A) e Tsa2 (B) previamente oxidadas com 1.2 equivalentes de H₂O₂ e Trx1 previamente reduzida por 30 min com 20 mM de DTT (o excesso de DTT foi retirado através de gel filtração) foram reagidas com Trx1 em excesso (8:1 equivalentes) e os dados de fluorescência intrínseca do triptofano (excitação 280 nm e emissão 340 nm) foram adquiridos em espectrofluorímetro com *stopped-flow*.

Cabe ressaltar que apesar de algumas constantes de redução já terem sido calculadas para algumas 2-Cys Prx, os trabalhos foram realizados com proteínas mutantes (Parsonage *et*

al., 2005) e revelaram taxas de redução bastante significativas ($\sim 10^7 \text{ M}^{-1}\text{s}^{-1}$). As taxas de redução da metionina sulfóxido redutase (MSR) pela Trx de *E. coli* foi determinada pela mesma metodologia e microcalorimetria e os autores concluíram que o passo limitante da velocidade para a regeneração da forma reduzida de MSR por Trx foi a dissociação do complexo entre Trx oxidada e MSR reduzida (Antoine, Boschi-Muller e Branlant, 2003). Adicionalmente, já foi demonstrado que a formação do dissulfeto em 2-Cys Prx pode ser um processo lento com taxas que variam de 75 s^{-1} (AhpC de *Salmonella typhimurium*) a 1.7 s^{-1} (Prx2 de *Homo sapiens*) (Parsonage *et al.*, 2015; Peskin *et al.*, 2013).

Neste contexto, uma vez que as constantes para decomposição de H_2O_2 e CHP e a redução de Trx1/Trx2 por TrxR1 residem na ordem de $10^7 \text{ M}^{-1}\text{s}^{-1}$ (Oliveira *et al.*, 2010) e as constantes de redução de Tsa1 e Tsa2 por Trx1 são de $10^6 \text{ M}^{-1}\text{s}^{-1}$, é pertinente supor que as taxas determinadas para decomposição de hidroperóxidos por cinética de estado estacionário utilizando o sistema Trx ($10^{4-5} \text{ M}^{-1}\text{s}^{-1}$) possam estar sob influencia de fenômenos não excludentes como: 1) lentidão da formação de dissulfeto de Tsa1 e Tsa2 no processo de condensação; 2) dissociação do complexo entre Trx oxidada e Tsa1 reduzida e 3) superoxidação de parcela de Tsa1 e Tsa2 nas reações. A hipótese de superoxidação foi avaliada e os dados são apresentados a seguir.

Tabela 2. Determinação dos parâmetros cinéticos de Tsa1 e Tsa2 para substratos oxidantes (H_2O_2 , *t*-BOOH e CHP) e para os substratos redutores Trx1 e Trx2

* Condições para determinação dos parâmetros cinéticos:

Substratos oxidantes: Tsa2 (1 μM), Trx1 ou Trx2 (2 μM), TrxR1 (0.3 μM), NADPH (150 μM) e concentrações variáveis de hidroperóxidos.

Substratos redutores: Tsa2 (1 μM), TrxR1 (0.3 μM), NADPH (150 μM), H₂O₂ (500 μM) e concentrações variáveis de Trx1 ou Trx2.

5.2 CAPÍTULO 2 - Susceptibilidade de Tsa1 e Tsa2 a superoxidação por diferentes peróxidos

5.2.1 Avaliação da susceptibilidade a superoxidação de Tsa1 e Tsa2 utilizando ensaio de NADPH e SDS-PAGE

Para se avaliar comparativamente a superoxidação de Tsa1 e Tsa2 na presença de altas doses de hidroperóxidos foram realizados ensaios de oxidação do NADPH utilizando o sistema Trx. Foram realizados experimentos utilizando como substrato redutor Trx1 ou Trx2 e como substrato oxidante altas concentrações de H₂O₂, CHP e *t*-BOOH (250 μM, 500 μM, 1 mM, 5 mM e 10 mM). Neste contexto, a inibição do consumo de NADPH indica de forma indireta a formação de espécies superoxidadas em C_P-SO₂H ou C_P-SO₃H, o que impossibilita a redução por Trx e consequentemente o consumo de NADPH (Ikeda *et al.*, 2011; Nelson *et al.*, 2013). A figura 17 demonstra os resultados destes experimentos para as proteínas Tsa1 e Tsa2 utilizando Trx1 como substrato redutor e H₂O₂, CHP e *t*-BOOH como substratos oxidantes.

Analizando o resultado desse experimento pode-se observar que quando o substrato utilizado é a H₂O₂ a reação da proteína Tsa1 (Figura 17A) é inibida com concentrações superiores a 500 μM de substrato, ao passo que a reação de Tsa2 apresenta uma inibição quase imperceptível (Figura 17B). Já quando o CHP é utilizado como substrato à reação com Tsa1 é inibida na concentração mínima testada (250 μM), sendo que a enzima apresenta-se praticamente inativa (Figura 17C), enquanto que nas mesmas condições Tsa2 apresentou uma inibição muito menor (Figura 17D). Quando se utilizou o *t*-BOOH como substrato oxidante verificou-se uma inibição intermediária (Figura 17E e 17F), sendo que utilizando este substrato a reação de Tsa2 também apresentou uma menor inibição.

Foram realizados também experimentos semelhantes utilizando Trx2 como substrato redutor, os resultados demonstraram diferenças pouco significativas quando comparados à utilização de Trx1 (Figura 18). Tsa1 novamente apresentou uma maior inibição quando comparada a Tsa2 e a inibição apresenta aumento significativo quando o substrato utilizado é um peróxido orgânico (CHP ou *t*-BOOH). Os resultados obtidos nestes experimentos revelam que ocorre uma superoxidação diferencial entre Tsa1 e Tsa2 e que peróxidos orgânicos promovem esse processo mais eficientemente que o H₂O₂.

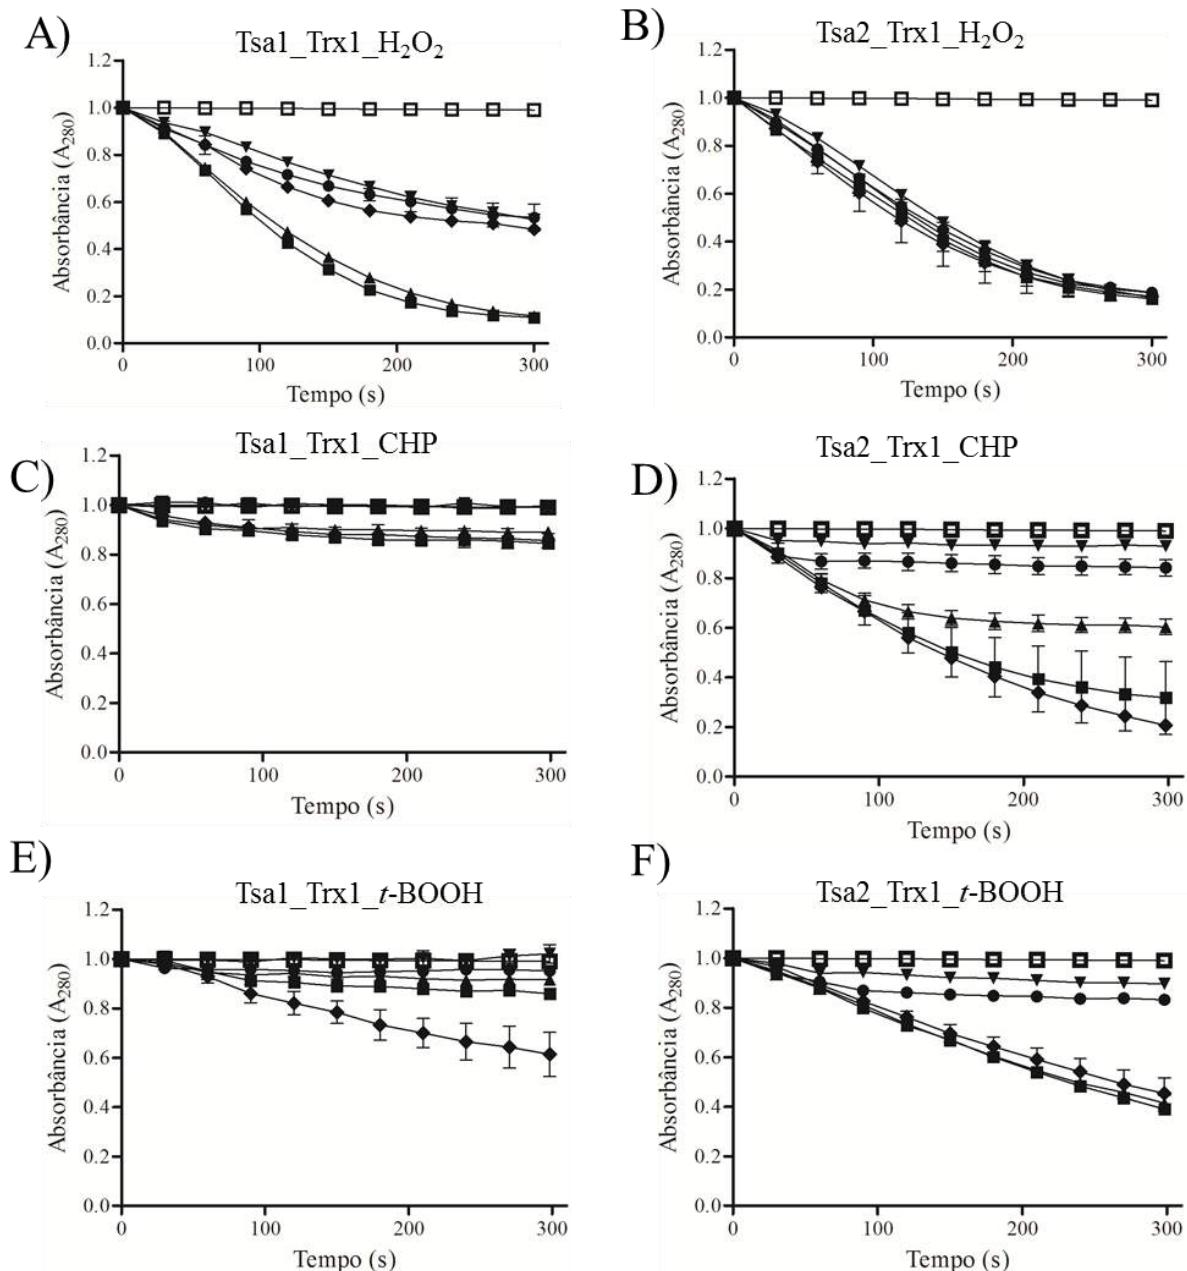

Figura 17. Susceptibilidade a superoxidação de Tsa1 e Tsa2. A atividade peroxidásica de Tsa1 (A, C e E) e Tsa2 (B, D e F) foi monitorada através da oxidação do NADPH (340 nm) com concentrações crescentes de hidroperóxidos: 0 μ M, (\square), 250 μ M (\blacklozenge), 500 μ M (\blacksquare), 1 mM (\blacktriangle), 5 mM (\bullet), 10 mM (\blacktriangledown). A reação (100 μ l) foi realizada em tampão 50 mM Hepes-NaOH contendo 1 mM de azida, 100 μ M de DTPA na presença de 150 μ M de NADPH, 1 μ M de Tsa1 ou Tsa2, 2 μ M de Trx1, 0,3 μ M de TrxR1 e diferentes concentrações de hidroperóxido. A reação foi iniciada pela adição do hidroperóxido. As curvas representam a oxidação do NADPH em diferentes concentrações de H₂O₂ (A e B), CHP (C e D) e *t*-BOOH (E e F).

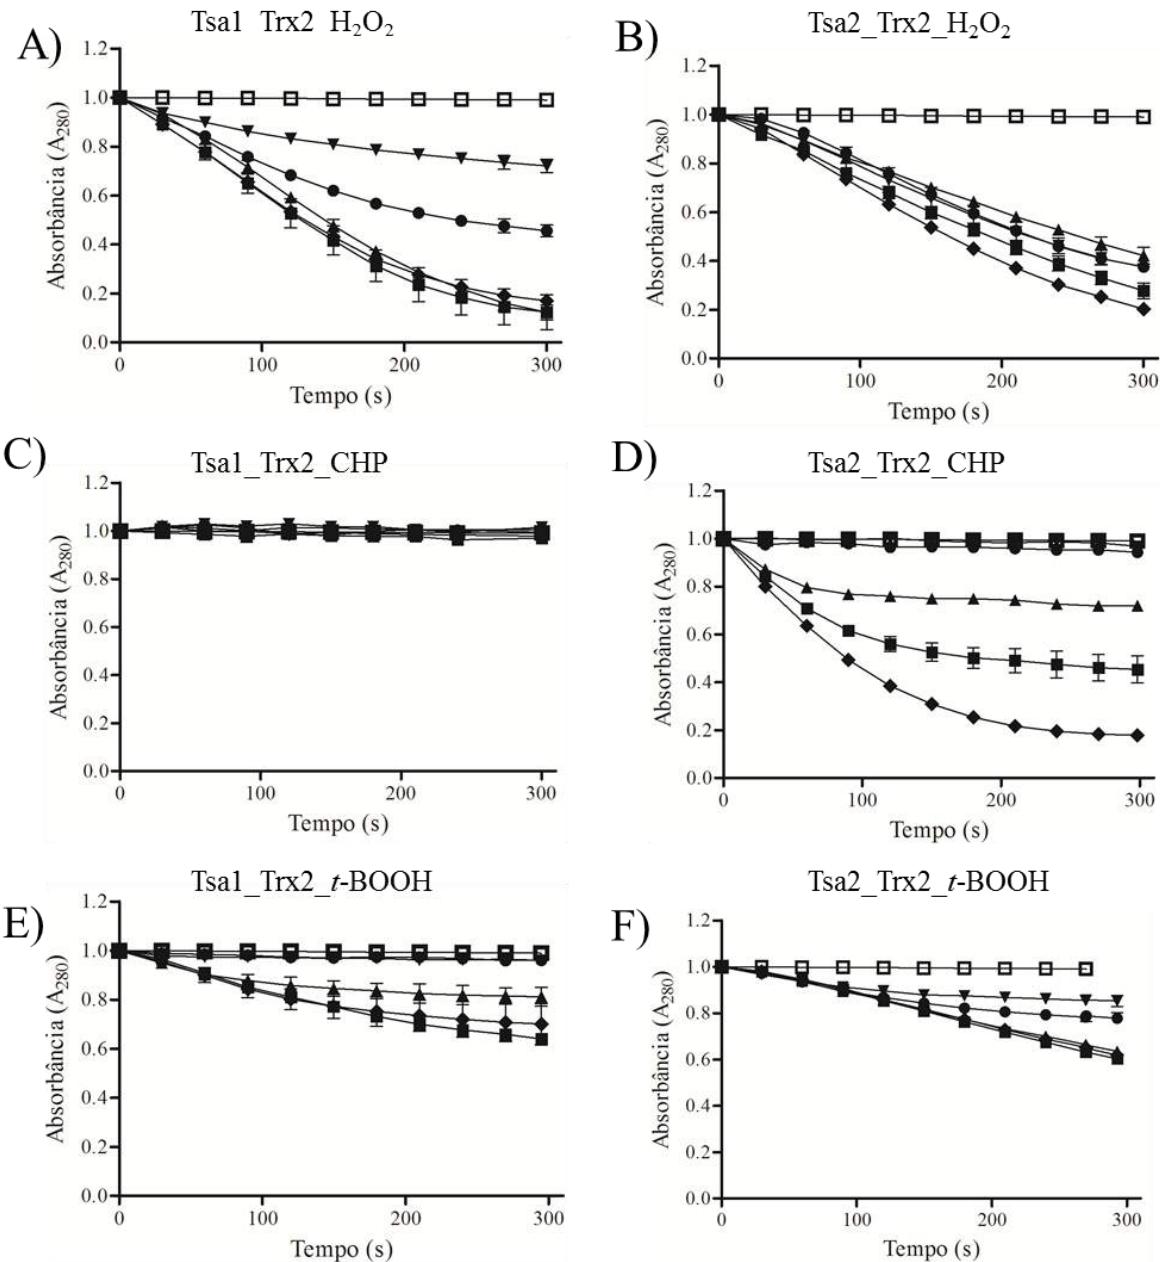

Figura 18. Susceptibilidade a superoxidação de Tsa1 e Tsa2. A atividade peroxidásica de Tsa1 (A, C e E) e Tsa2 (B, D e F) foi monitorada através da oxidação do NADPH (340 nm) com concentrações crescentes de hidroperóxidos: 0 μM (□), 250 μM (◆), 500 μM (■), 1 mM (▲), 5 mM (●), 10 mM (▼). A reação (100 μl) foi realizada em tampão 50 mM Hepes-NaOH contendo 1 mM de azida, 100 μM de DTPA na presença de 150 μM de NADPH, 1 μM de Tsa1 ou Tsa2, 2 μM de Trx2, 0,3 μM de TrxR1 e diferentes concentrações de hidroperóxidos. A reação foi iniciada pela adição do hidroperóxido. As curvas representam a oxidação do NADPH em diferentes concentrações de H₂O₂ (A e B), CHP (C e D) e t-BOOH (E e F).

A superoxidação da C_P pode ser também observada por SDS-PAGE através do monitoramento da forma dimérica e monomérica das 2-Cys Prx (Nelson *et al.*, 2013; Perkins *et al.*, 2013). Em reações com concentrações baixas de hidroperóxidos e presença de sistema redutor ocorre o predomínio da forma reduzida da proteína, o que pode ser observado em SDS PAGE como monômeros de ~23 kDa (Figura 19), quando há um aumento na concentração de

hidroperóxidos ocorre um predomínio de formas diméricas ($C_P S - SC_R$), pois há formação de dímeros mantidos por ligação dissulfeto entre C_P e C_R de diferentes monômeros (Figura 19). Por fim, quando ocorre a superoxidação moderada (formação de espécies $C_P SO_2 H$ ou $C_P SO_3 H$) podem ser observadas duas diferentes formas em SDS-PAGE, dimérica e monomérica. Na forma dimérica ocorre a superoxidação de apenas uma subunidade do dímero, sendo que a outra permanece em dissulfeto, esse estado aumenta a resistência da migração no SDS-PAGE fazendo com que a proteína apareça levemente superior a forma oxidada. Já a forma monomérica apresenta superoxidação de ambas as C_P do dímero, o que acarreta na sua dissociação em SDS-PAGE. Esta forma é esperada em altas concentrações de hidroperóxidos (Figura 19).

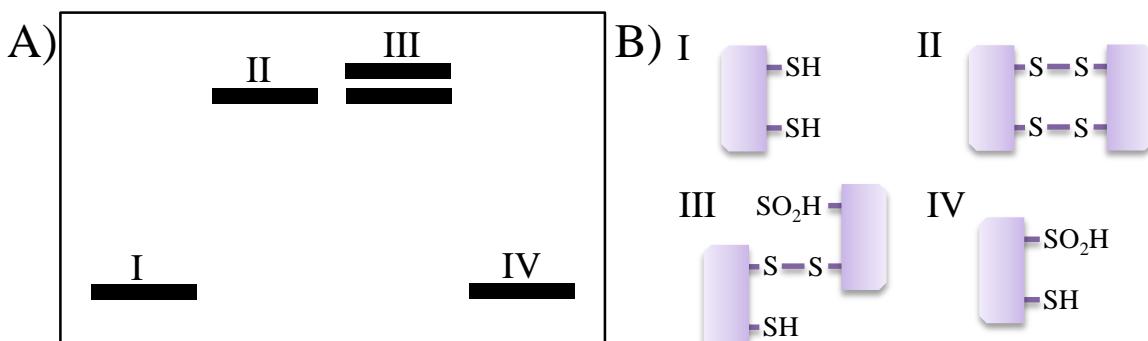

Figura 19. Diagrama exemplificando o resultado em SDS-PAGE de formas reduzidas, oxidadas e superoxidadas e formação de dissulfetos de Prx 2-Cys típica. Em A) e B) as representações são: I) 2-Cys Prx na forma reduzida, detectada como monômero. II) Representação da forma oxidada, detectada como dímero. III) Forma dimérica oxidada em dissulfeto (banda inferior) e dimérica com uma C_P superoxidada (superior). IV) Forma monomérica com ambas as C_P superoxidadas.

Para verificar através de SDS-PAGE o nível de superoxidação de Tsa1 e Tsa2 foram realizados ensaios de oxidação de NADPH semelhante aos ensaios de superoxidação descritos acima, no entanto a concentração de Tsa1 e Tsa2 utilizada foi de 9.3 μM para possibilitar a detecção em SDS-PAGE. Os experimentos foram realizados com concentrações crescentes de hidroperóxidos (10 μM a 10 mM), sendo que após 30 minutos de reação, foram adicionados a cada reação 100 mM de NEM, ao qual é um agente alquilante que se liga a cisteínas livres impedindo a formação de dissulfetos artefatuais.

Para reações utilizando H_2O_2 as proteínas Tsa1 e Tsa2 apresentaram comportamentos bastante similares quando comparadas (Figura 20A e 20B), Tsa1 apresentou formas reduzidas nas reações que continham até 75 μM de H_2O_2 , indicando que até essa concentração de substrato oxidante a enzima foi capaz de degradar sem a ocorrência de superoxidação de C_P . Em concentrações entre 125 μM e 1 mM ocorreu a predominância de dímeros, o qual representa a proteína oxidada em dissulfeto, já na concentração de 1 mM já é possível

verificar o surgimento de uma banda correspondente ao monômero, a qual representa a forma superoxidada, sendo possível verificar um aumento gradativo da intensidade desta banda quando a concentração de H₂O₂ é aumentada. Tsa2 apresentou formas reduzidas até concentração de 50 μM e espécies superoxidadas são visualizadas a partir da concentração de 1 mM de H₂O₂. Ensaios utilizando CHP como substrato oxidante demonstraram que Tsa1 sofre uma superoxidação muito acentuada não sendo possível verificar a concentração exata onde inicia a superoxidação, desde a concentração mais baixa de CHP já é possível verificar bandas diméricas, as quais possivelmente representam dímeros contendo apenas uma ligação dissulfeto e uma cisteína superoxidada (Figura 20C).

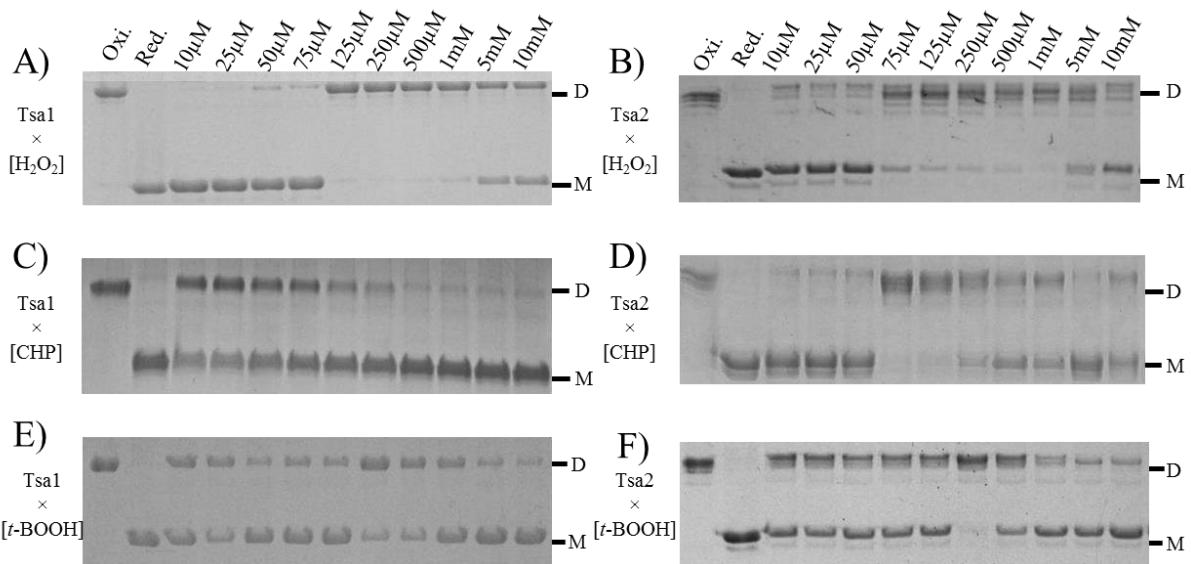

Figura 20. Ensaio de superoxidação de Tsa1 e Tsa2 utilizando sistema Trx (Trx1) na presença de concentrações crescentes de hidroperóxidos. O estado oligomérico de Tsa1 (A, C e E) e Tsa2 (B, D e F) foi monitorado através de SDS-PAGE em condições não redutoras. As reações foram realizadas em tampão 50 mM Hepes-NaOH pH 7.4 contendo 100 μM de DTPA, 1 mM de azida, 150 μM de NADPH, 9.3 μM de Tsa1, 1 μM de Trx1, 0.3 μM de TrxR1 e concentrações crescentes de hidroperóxidos (10 μM – 10 mM). A e B: H₂O₂; C e D: CHP e E e F: t-BOOH. As reações foram iniciadas pela adição do hidroperóxido, mantidas a 30 °C por 30 minutos e alquiladas com 100 mM de NEM por 30 min. Em seguida as amostras foram aplicadas em SDS-PAGE em condições não redutoras. As legendas do lado direito das figuras denotam a enzima e o peróxido utilizado e do lado direito: M = monômero, D = dímero.

O experimento realizado com a proteína Tsa2 utilizando CHP como substrato oxidante demonstrou que Tsa2, possui maior resistência a superoxidação por CHP, sendo possível verificar formas superoxidadas a partir da concentração de 250 μM (Figura 20D). Com relação à utilização com t-BOOH, ambas as proteínas apresentaram alto nível de superoxidação, Tsa1 apresentou superoxidação com 250 μM e Tsa2 a partir de 500 μM (Figura 20E e 20F).

Para verificar se o nível de superoxidação pode ser alterado pelo substrato redutor experimentos semelhantes foram realizados utilizando Trx2 e concentrações crescentes de

H_2O_2 , CHP e *t*-BOOH como substratos oxidantes. Os resultados foram equivalentes aos obtidos utilizando Trx1 como substrato redutor (Figura 21).

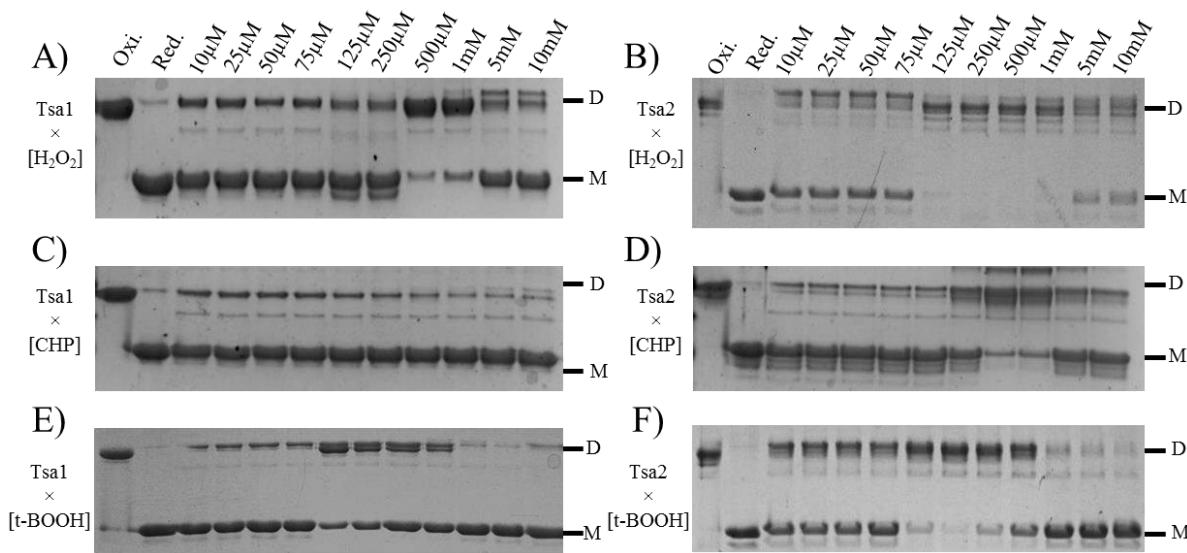

Figura 21. Ensaio de superoxidação de Tsa1 e Tsa2 utilizando sistema Trx (Trx2) na presença de concentrações crescentes de hidroperóxidos. O estado oligomérico de Tsa1 (A, C e E) e Tsa2 (B, D e F) foi monitorado através de SDS-PAGE em condições não redutoras. As reações foram realizadas em tampão 50 Hepes-NaOH pH 7.4 contendo 100 μM de DTPA, 1 mM de azida, 150 μM de NADPH, 9.3 μM de Tsa1, 1 μM de Trx2, 0.3 μM de TrxR1 e concentrações variáveis de hidroperóxidos (10 μM – 10 mM) A e B: H_2O_2 ; C e D: CHP e E e F: *t*-BOOH. por 30 min. Em seguida as amostras foram aplicadas em SDS-PAGE em condições não redutoras. As legendas do lado direito das figuras denotam a enzima e o peróxido utilizado e do lado direito: M = monômero, D = dímero.

Para confirmar a superoxidação das proteínas foram realizados experimentos de *western blot* com anticorpo para a forma Prx-SO_{2/3}, entretanto esse anticorpo não apresentou especificidade para as espécies superoxidadas, sendo reativo também com a forma reduzida e oxidada da proteína (dados não apresentados).

Os experimentos de cinética enzimática utilizando H_2O_2 e peróxidos orgânicos juntamente com os experimentos de superoxidação demonstram que hidroperóxidos orgânicos tais como CHP e *t*-BOOH são capazes de promover mais eficientemente a superoxidação quando comparados ao H_2O_2 . Outra observação importante verificada nestes experimentos é que Tsa2 é mais resistente a superoxidação que Tsa1, de fato este resultado demonstra uma diferença bastante significativa entre essas proteínas. Por outro lado o passo de redução de Tsa1 e Tsa2 não apresentou diferenças significativas quando os ensaios foram realizados com Trx1 ou Trx2, confirmando os dados cinéticos.

5.2.2 Avaliação da superoxidação da C_P por meio de ensaios envolvendo alterações de fluorescência do triptofano

Como mencionado anteriormente, as constantes de pseudo-primeira ordem para as proteínas Tsa1 e Tsa2 para H₂O₂ e CHP foram determinadas por experimentos fluorométricos. Um fenômeno importante observado foi que logo após a queda de fluorescência causada pela oxidação da C_P ocorreu um aumento na emissão de fluorescência para Tsa1 (Figura 22A) que não foi observada para Tsa2 (Figura 22B). Cabe ressaltar que a razão de hidroperóxido para proteína utilizada foi de 10:1 equivalentes molares. Experimentos adicionais utilizando diferentes concentrações de hidroperóxidos revelaram que esta segunda fase da reação é dependente da concentração de hidroperóxido (Figura 22C), entretanto quando Tsa2 foi submetida às mesmas condições esta segunda fase não foi detectada mesmo em concentrações muito superiores de hidroperóxidos (50 equivalentes).

Neste contexto, uma das possibilidades para a segunda fase apresentada por Tsa1 poderia ser atribuída a superoxidação de C_P, uma vez que análises de estruturas criptográficas revelam que 2-Cys Prx no estado reduzido ou superoxidado apresentam conformação similar (Figura 22D), mas muito diferente da forma oxidada. Para avaliar se o retorno da fluorescência se tratava de superoxidação foram realizados ensaios fluorométricos de Tsa1 reduzida, oxidada com baixas doses de hidroperóxidos (1.2 eq.) ou superoxidada com o auxílio do sistema tiorredoxina. Para confirmar que o tratamento levou a superoxidação de Tsa1 foi realizado um ensaio comparativo em SDS-PAGE não redutor onde foram comparadas Tsa1 reduzida, oxidada, superoxidada, superoxidada após a adição de 10 mM de DTT e superoxidada após a adição de 1.2 equivalentes de H₂O₂. O resultado indica que mesmo após a adição de H₂O₂ a proteína manteve-se em monômero o que indica fortemente que se tratar da forma contendo C_P superoxidada (dados não apresentados).

Após a comprovação da superoxidação foi realizado um ensaio comparativo de fluorescência, onde foram comparadas a proteína Tsa1 previamente reduzida, oxidada e superoxidada como se pode observar na figura 22E ocorre um aumento de fluorescência quando a proteína se encontra superoxidada, o indica que o retorno de fluorescência se trata da formação de C_PSO_{2/3}. De fato, Reyes e colaboradores (2011) observam um fenômeno semelhante na 1-Cys Prx AhpE de *Mycobacterium tuberculosis*, e utilizaram essa retorno para determinar as constantes de superoxidação desta enzima. Tendo em vista os resultados obtidos e os dados presentes literatura, consideramos que o retorno da fluorescência representa superoxidação de C_P de Tsa1. Assim foram determinadas as constantes de pseudo-

primeira ordem para superoxidação de Tsa1 por H_2O_2 e CHP (Figura 22F), sendo obtida uma constante de $6.43 \times 10^5 \text{ M}^{-1}\text{s}^{-1}$ para H_2O_2 e $8.12 \times 10^5 \text{ M}^{-1}\text{s}^{-1}$ para CHP. De fato, apesar destas taxas de superoxidação se apresentarem bastante elevadas elas são muito similares ao determinado previamente para AhpE ($10^5 \text{ M}^{-1}\text{s}^{-1}$) (Reyes *et al.*, 2011). Neste contexto, os dados obtidos por ensaios fluorométricos utilizando baixas doses de hidroperóxidos estão de acordo com os observados por cinética de estado estacionário utilizando o sistema Trx que indicam uma maior suscetibilidade a superoxidação C_P de Tsa1 quando comparada a Tsa2 (Figuras 17, 18, 20 e 21).

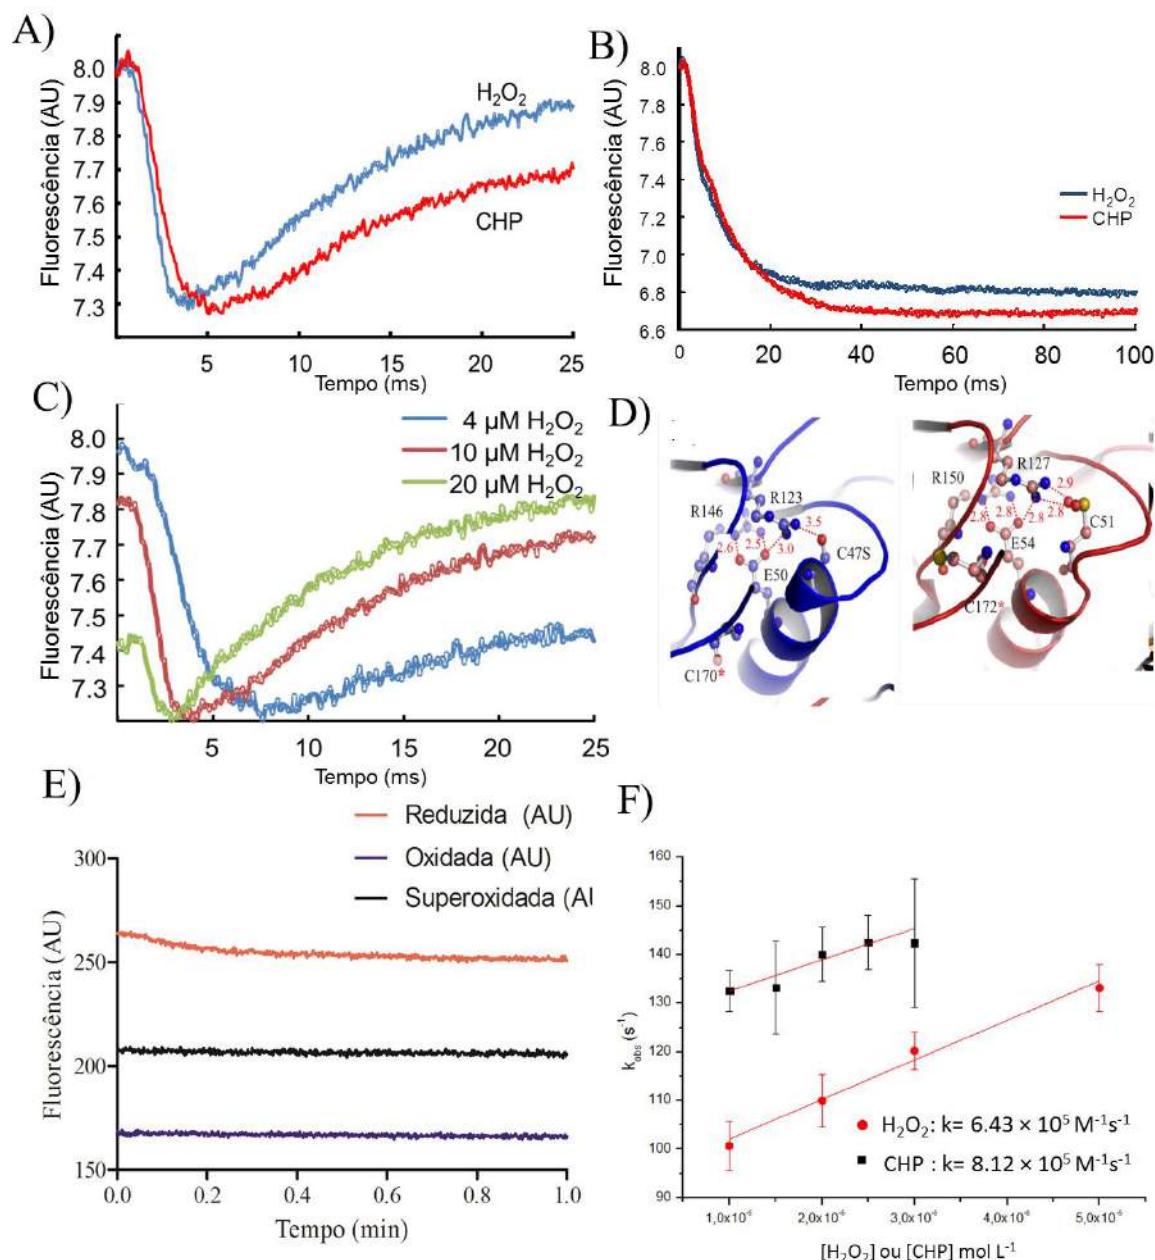

Figura 22. Análises de superoxidação de Tsa1 e Tsa2 através de fluorometria. A) Espectro de fluorescência de Tsa1 (1μM) previamente reduzida com 20 mM de DTT (excesso removido através gel filtração) e reagida com H_2O_2 (linha azul) ou CHP (10μM) (linha vermelha). Nota-se o aumento de fluorescência após a fase de redução do peróxido. B) Espectro de fluorescência de Tsa2 (1μM) foi reagida com H_2O_2 (linha azul) ou CHP (10μM) (linha vermelha).

(linha vermelha) ($10\mu\text{M}$). C) Emissão de fluorescência de Tsa1 em doses crescentes de peróxido de hidrogênio (4, 10 e $20\mu\text{M}$), demonstrando a dose dependência do aumento de fluorescência. D) Estruturas cristalográficas de Tsa1^{C47S} (código de pdb: 3SBC) que mimetiza a forma reduzida (azul) e Prx2 de *H. sapiens* com C_P superoxidata em C_P-SO₂H (1QMV). E) Espectro de emissão de fluorescência da forma reduzida, oxidada e superoxidata de Tsa1 ($\lambda_{\text{ex}} = 280$ e $\lambda_{\text{em}} = 340$ nm. F) Valores de k_{obs} foram plotados em relação à concentração de H₂O₂ e CHP utilizadas e demonstram que a inclinação da reta é dependente da concentração de hidroperóxido.

Curiosamente, análises efetuadas por SDS-PAGE, utilizando tratamentos com altas doses de hidroperóxidos não revelam a formação de espécies superoxidadas de Tsa1 ou Tsa2 mesmo com altas doses (100 eq.) de hidroperóxidos (Figura 23) o que pode indicar que a superoxidação detectada por experimentos fluorométricos representa somente uma pequena parcela da população de enzimas presentes na reação. De fato, mesmo em altas doses de hidroperóxido não foi possível à detecção em SDS-PAGE de espécies superoxidadas quando além de altas doses de hidroperóxidos foi adicionado o sistema tiorredoxina, sugerindo que esta age como um catalisador para a superoxidação das Prx.

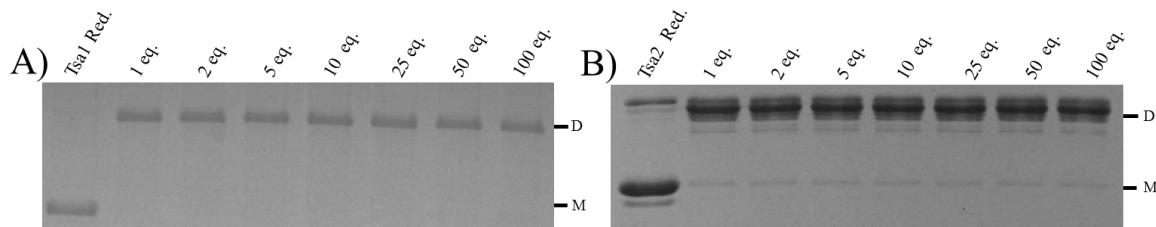

Figura 23. Ensaio de susceptibilidade a superoxidação de Tsa1 e Tsa2 com CHP sem a presença do sistema Trx. Tsa1 e Tsa2 foram previamente reduzidas com 20 mM de DTT (excesso de DTT retirado por gel filtração), e foram adicionadas concentrações crescentes de CHP (1-100 equivalentes). Em seguida as amostras foram aplicadas em SDS-PAGE em condições não redutoras. As legendas superiores denotam a enzima e as concentrações equimolares de CHP adicionadas a reação, ao lado direito: M = monômero, D = dímero.

5.2.3 Influencia a substituição Thr/Ser no processo de superoxidação

Tsa1 e Tsa2 possuem uma grande semelhança estrutural e algumas diferenças funcionais, a que mais merece destaque está relacionada à maior resistência de Tsa2 a superoxidação. Análises da região do sítio ativo revelam que a diferença mais marcante reside na substituição de uma Thr em Tsa1 por uma Ser em Tsa2. De fato a análise da região contendo a tríade catalítica da estrutura cristalográfica de Tsa1 (Figura 24A) com um modelo teórico de Tsa2 (Figura 24B) revela que a única diferença encontrada na rede de interações polares efetuada pelos resíduos da tríade catalítica reside em uma interação do tipo CH- π realizado pelo C γ de Thr o qual é inexistente para Tsa2.

Neste contexto, para uma análise comparativa da influência da substituição Thr/Ser foi gerado o mutante Tsa2^{S44T} bem como foi utilizado o mutante Tsa1^{T44S} obtido previamente em outra investigação do nosso grupo (Apêndice A).

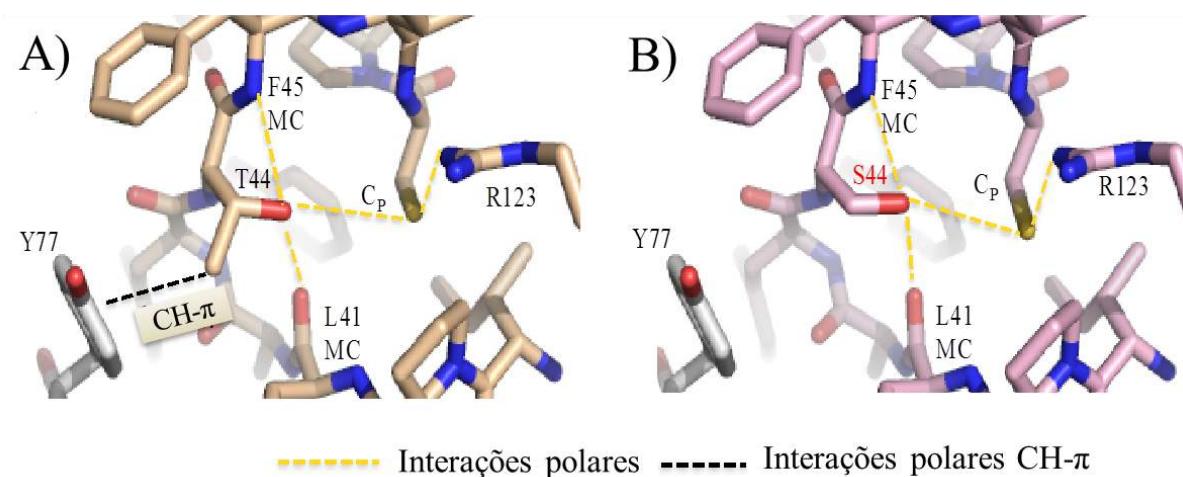

Figura 24. Diferenças de interações dos aminoácidos da tríade catalítica entre Tsa1 e Tsa2. (A) Estrutura cristalográfica de Tsa1 (1SBC) e (B) Modelo teórico de Tsa2 mostrando a rede de interações polares entre aminoácidos da tríade catalítica (C_p , Thr/Ser e Arg). As estruturas estão representadas em sticks e coloridas em CPK (N=azul, O= vermelho e S=laranja claro). Os carbonos em Tsa1 estão representados em bege e de Tsa2 em rosa.

Incialmente foram realizados ensaios de oxidação do NADPH em concentrações crescentes de H_2O_2 e CHP. Para efeitos comparativos os resultados apresentados anteriormente para as proteínas selvagens serão apresentados novamente. Os resultados revelaram que a substituição da Thr da tríade catalítica em Tsa1, mutante $Tsa1^{T44S}$, levou a uma maior resistência à superoxidação (Figuras 25C e 25D) quando comparado com a proteína Tsa1 selvagem (Figuras 25A e 25B), tanto para H_2O_2 quanto para CHP. De fato esta única substituição de aminoácido deixou o comportamento de Tsa1 muito similar ao observado para Tsa2 selvagem (Figuras 25E e 25F). Por outro lado o mutante $Tsa2^{S44T}$ apresentou maior susceptibilidade a superoxidação (Figura 25G e 25H), resultados muito semelhantes aos observados para a proteína Tsa1 (Figura 25A e 25B).

Para uma análise mais elaborada da susceptibilidade a superoxidação dos mutantes $Tsa1^{T44S}$ e $Tsa2^{S44T}$ também foram realizados ensaios utilizando SDS-PAGE. Novamente, para termos comparativos os resultados das proteínas selvagens são reapresentados para maior clareza. Como pode ser observado na figura 26 o mutante $Tsa1^{T44S}$ apresenta maior resistência a superoxidação quando comparado ao selvagem, na reação com H_2O_2 bandas monoméricas superoxidadas são visualizadas a partir da concentração de 5 mM (Figura 26C). Já em reações com CHP bandas superoxidadas são visualizadas a partir de concentrações de 250 μ M (Figura 26D). Novamente os dados são bastante contrastantes com os obtidos para a proteína selvagem (Figura 26A e 26B) e remetem aos dados obtidos para Tsa2 selvagem (Figura 26E e 26F) o que indica que esta substituição no sitio ativo deixa a enzima muito mais resistente a superoxidação da C_p . Por outro lado o mutante $Tsa2^{S44T}$ apresentou um aumento da

susceptibilidade a superoxidação uma vez que espécies superoxidadas são observadas em menores concentrações de hidroperóxidos (Figura 26G e 26H). Novamente quando o CHP (Figura 26) é utilizado como substrato, a superoxidação é extremamente evidente mesmo em doses baixas de CHP de forma muito semelhante ao observado para a proteína Tsa1 (Figura 26B).

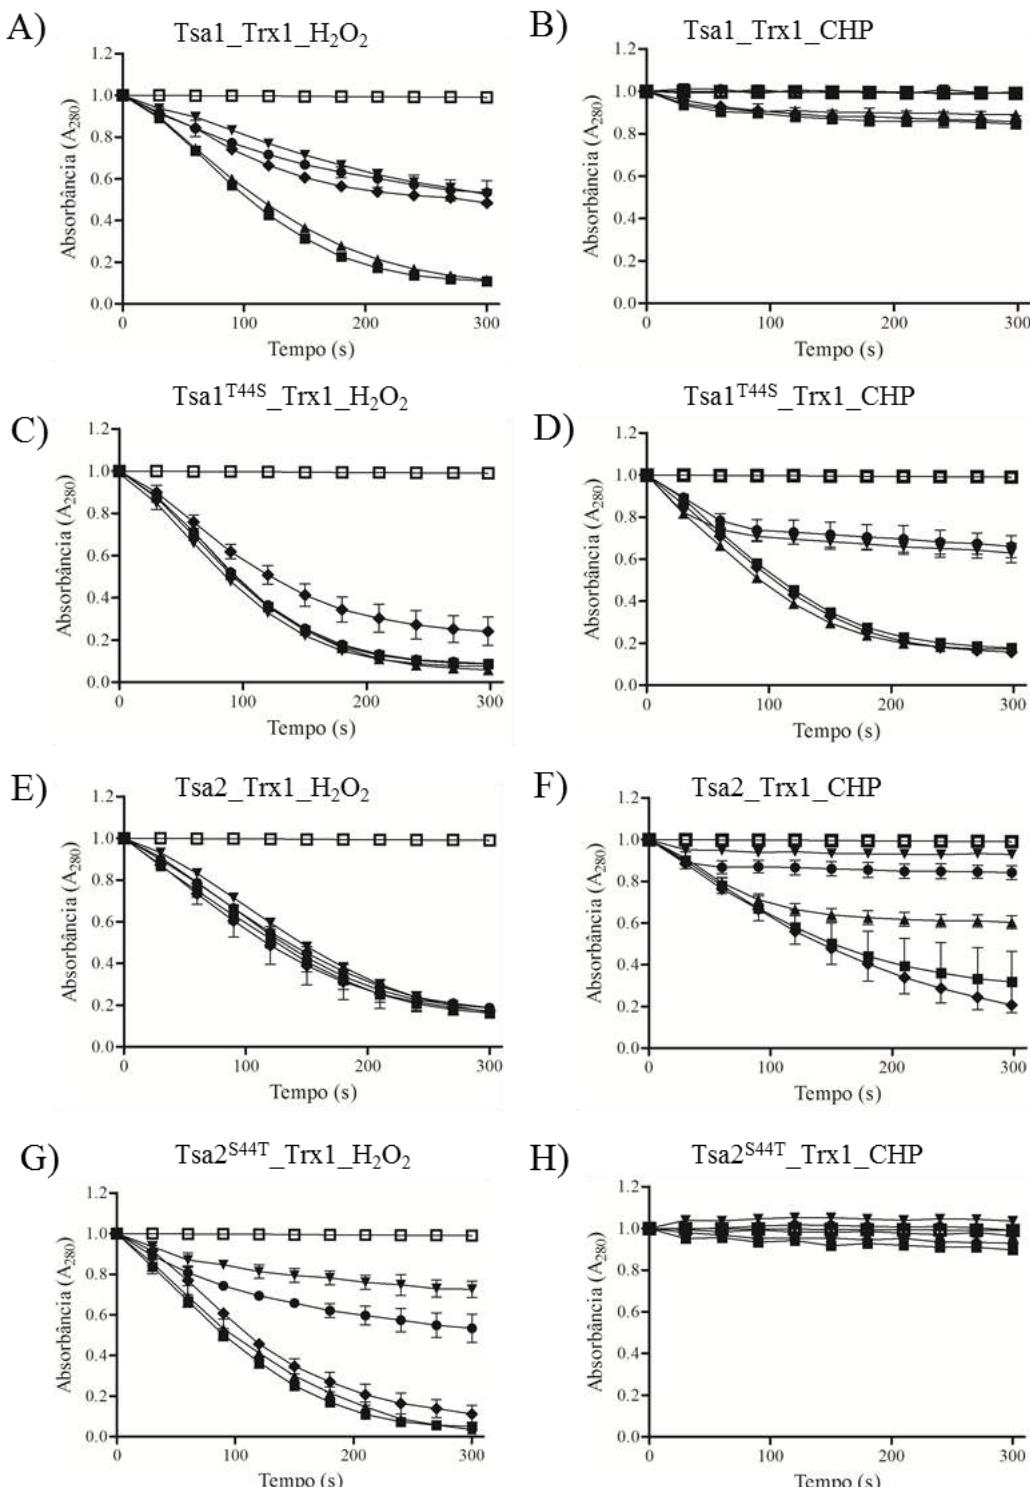

Figura 25. Susceptibilidade a superoxidação de Tsa1, Tsa2, Tsa1^{T44S}, Tsa2^{S44T}. A atividade peroxidásica de Tsa1 (A e B), Tsa1^{T44S} (C e D), Tsa2 (E e F) e Tsa2^{S44T} (G e H) foi monitorada através da oxidação do NADPH

(340nm) com concentrações crescentes de hidroperóxidos: 0 μ M (□), 250 μ M (◆), 500 μ M (■), 1 mM (▲), 5 mM (●), 10 mM (▼). A reação (100 μ l) foi realizada em tampão 50 mM Hepes-NaOH pH 7.4 contendo 1 mM de azida, 100 μ M de DTPA na presença de 150 μ M de NADPH, 1 μ M de Tsa1, Tsa2, Tsa1^{T44S} ou Tsa2^{S44T}, 2 μ M de Trx1, 0.3 μ M de TrxR1 e diferentes concentrações de hidroperóxidos. A reação foi iniciada pela adição do hidroperóxido. As curvas representam a oxidação do NADPH em diferentes concentrações de H₂O₂ (A, C, E e G) e CHP (B, D, F e H).

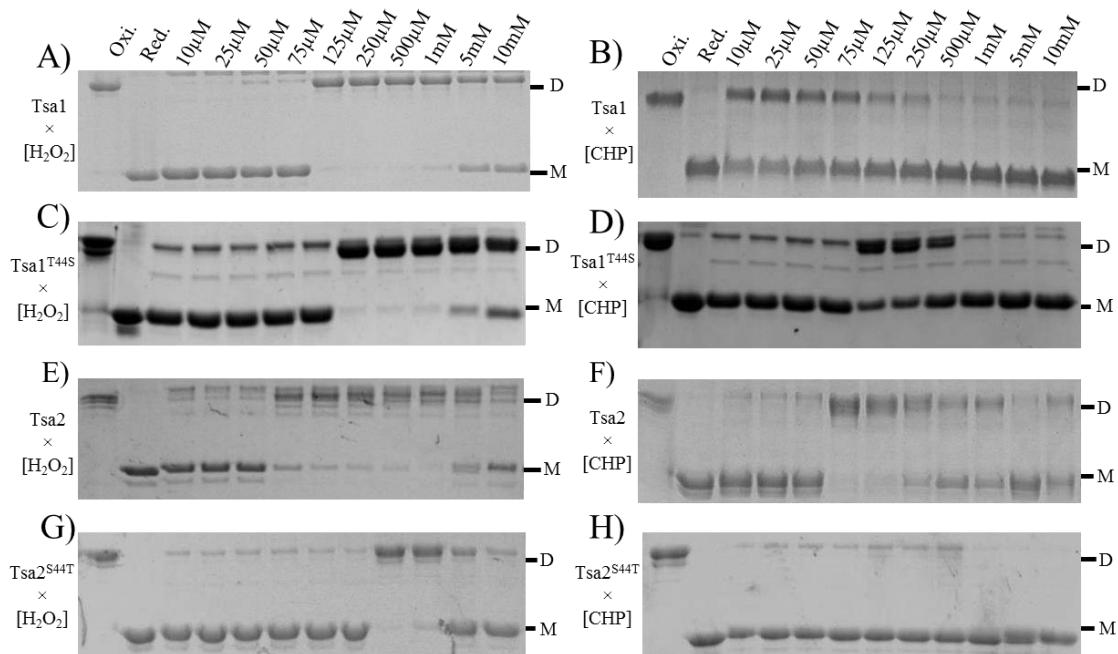

Figura 26. Ensaio de superoxidação de Tsa1, Tsa1^{T44S}, Tsa2 e Tsa2^{S44T} utilizando sistema Trx na presença de concentrações crescentes de hidroperóxidos. O estado oligomérico de Tsa1 (A, B), Tsa1^{T44S} (C e D), Tsa2 (E e F) e Tsa2^{S44T} (G e H) foi monitorado através de SDS-PAGE em condições não redutoras. As reações foram realizadas em tampão 50 mM Hepes-NaOH pH 7.4 contendo 100 μ M de DTPA, 1 mM de azida, 150 μ M de NADPH, 9.3 μ M de Prx, 1 μ M de Trx1, 0.3 μ M de TrxR1 e concentrações variáveis de H₂O₂ (A, C, E e G) e CHP (B, D, F e H). As reações foram iniciadas pela adição do hidroperóxido, mantidas a 30 °C por 30 minutos e alquiladas com 100 mM de NEM. Após a reação as amostras foram aplicadas em SDS-PAGE em condições não redutoras. M = monômero, D = dímero.

Os resultados obtidos revelam de forma bastante clara que o resíduo da tríade catalítica o qual é substituído entre Tsa1 (Thr) e Tsa2 (Ser) apresenta um papel de grande importância para a suscetibilidade ou resistência a superoxidação. De fato análises de sequências de 2-Cys Prx típicas revelam que substituições naturais da Thr da tríade catalítica não é comum em organismos eucariotos, sendo encontrada somente em uma espécie de formiga (*Harpegnathos saltator*). Entretanto, esta substituição é encontrada em diversas 2-Cys Prx típicas de bactérias (AhpC) (Figura 27) o que pode indicar que esta robustez à superoxidação, em especial a peróxidos orgânicos pode estar relacionado a uma maior resistência a processos de peroxidação lipídica nos quais estes organismos podem estar envolvidos.

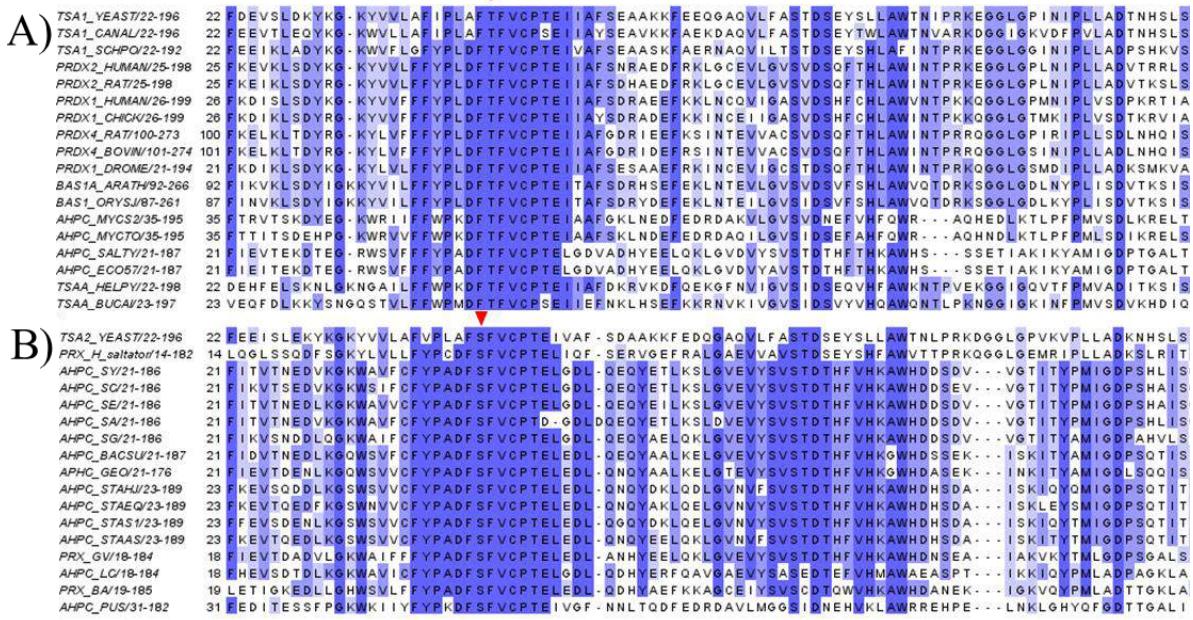

Figura 27. Alinhamento de estruturas de 2-Cys Prx típicas que contém Thr/Ser no sítio ativo e aminoácidos aromáticos na posição de interface decamérica. As sequências foram alinhadas utilizando o programa ClustalX (figura gerada pelo Jalview). Os aminoácidos destacados pelo retângulo vermelho destacam a conservação da Thr/Ser e de aminoácidos aromáticos na posição similar a Tyr77. 5.3 CAPÍTULO 3 - Influência da superoxidação na formação de estruturas de alto peso molecular em Tsa1 e Tsa2

Trabalhos da literatura demonstram que 2-Cys Prx são capazes de formar estruturas de alto peso molecular (HMW) (Angelucci *et al.*, 2013; Jang *et al.*, 2004; Meissner *et al.*, 2007; Saccoccia *et al.*, 2012). Estas estruturas podem apresentar função de chaperona molecular e aparentemente estão envolvidas na transdução de sinal, sua função é dependente da superoxidação da C_P, pH e choque térmico (Jang *et al.*, 2004; Radjainia *et al.*, 2015; Saccoccia *et al.*, 2012). Jang e colaboradores demonstraram em um trabalho pioneiro a formação HMW da proteína Tsa1 com função de chaperona molecular dependente de superoxidação ou choque térmico. Neste mesmo trabalho os autores relatam que Tsa2 é capaz de formar de formar HMW semelhantes a Tsa1, mas os resultados não são apresentados no artigo. Tendo em vista os resultados obtidos neste trabalho, a formação de complexos HMW de Tsa1 e Tsa2 foram analisadas em detalhes.

Inicialmente, com o objetivo de verificar possíveis diferenças estruturais entre as proteínas Tsa1 e Tsa2 foram realizados experimentos de SEC e DLS com as proteínas na forma reduzida (5 mM TCEP) e oxidada (1.2 equivalentes de H₂O₂) em concentração de 1 mg/mL (43.6 µM). Experimentos utilizando SEC demonstraram que a proteína Tsa1 na forma reduzida apresenta um pico de eluição, o qual representa o peso molecular aproximado de um decâmero, já na forma oxidada ocorre também à predominância de decâmeros, mas é observada uma parcela proteica na forma dimérica (Figura 28).

Experimentos de SEC com a proteína Tsa2 demonstraram que na concentração testada, independente, do estado redox a proteína se apresenta na forma decamérica (Figura 28), diferentemente de Tsa1, que quando oxidada possui as duas formas: decamérica e dimérica. Outra importante observação demonstrada através dos experimentos de SEC está relacionada ao tempo de retenção das moléculas na coluna. Tsa1 apresentou eluição do pico de maior intensidade com 7.8 minutos, enquanto Tsa2 apresentou a eluição com 7.4. Como este pico representa estruturas decaméricas é verificada uma diferença estrutural interessante a qual pode representar diferentes níveis de relaxação da molécula.

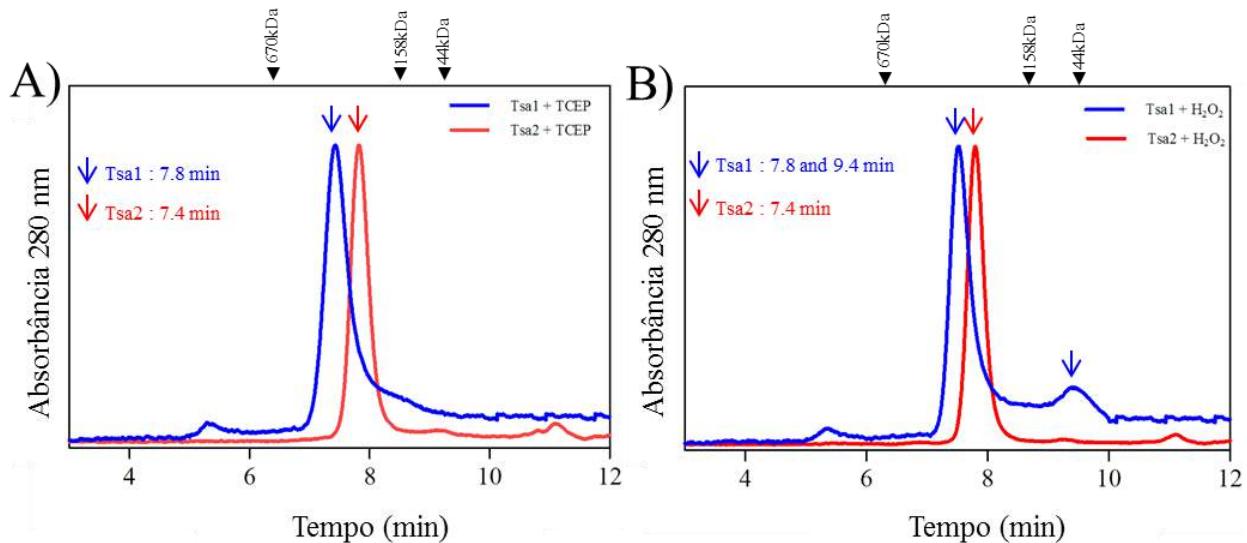

Figura 28. Cromatografia de exclusão molecular (SEC) de Tsa1 e Tsa2 nas formas reduzidas e oxidadas. Tsa1 e Tsa2 nas concentrações de 1mg/mL foram aplicadas em coluna Phenomenex BioSep-SEC-S 3000, a eluição dos componentes foi monitorada através da absorbância a 280 nm. Amostras de Tsa1 e Tsa2 foram reduzidas com 5 mM de TCEP (A) ou oxidadas com 1.2 equivalentes de H₂O₂ (B). Os padrões de peso molecular são representados na parte superior dos cromatogramas: tiroglobulina (bovina) (670 kDa), γ-globulina (bovina) (158 kDa), ovalbumina (frango) (44 kDa). Representações gráficas foram geradas utilizando GraphPad Prism 4.0. Para motivo de comparação dos tempos de retenção, todos os cromatogramas estão normalizados.

Para comprovar os resultados obtidos foram realizados experimentos DLS nas mesmas condições utilizadas no SEC (Tabela 3). Para esses experimentos, Tsa1 na forma reduzida apresentou raio hidrodinâmico (R_h) de 6.835 nm (polidispersidade = 24.2% de massa = 99.8%) e na forma oxidada apresentou um R_h = 5.855 nm (polidispersidade = 9.8 % e massa = 53.8%). Os dados de DLS da proteína Tsa1 desmontaram que na forma reduzida a proteína se apresenta na forma decamérica como demonstrado nos experimentos de SEC. Já os dados da forma oxidada demostram que a proteína apresenta-se na forma decamérica, mas 46.1% da massa apresenta-se em uma segunda forma (R_h = 0.864 e polidispersidade = 10.4%), que provavelmente representa as estruturas diméricas. A proteína Tsa2 apresentou na forma reduzida R_h de 6.832 (polidispersidade = 11.9% e % de massa = 97.9) e para forma oxidada R_h de 5.506 nm (polidispersidade = 11.9% e % de massa = 100), esses dados demonstram que independente do estado redox Tsa2 apresenta-se decamérica nas condições testadas.

Tabela 3. Espalhamento dinâmico de luz (DLS) de Tsa1 e Tsa2 previamente reduzida com 50mM de TCEP ou oxidada com 1.2 equivalentes de H₂O₂.

	Tsa1		Tsa2	
	Reduzida	Oxidada	Reduzida	Oxidada
R_h (nm)	6.8	5.8/0.8	6.8	5.5
Mass (%)	99.8	53.8/46.1	97.9	100
Pd (%)	24.2	9.8/10.4	11.9	11.9

Como pode ser demonstrado pelos dados obtidos não foram detectados complexos de alto peso molecular nas enzimas oxidadas e reduzidas. Para analisar a formação de HMW foram então realizados ensaios de superoxidação em reações utilizando o sistema Trx em concentrações altas de H₂O₂ e CHP. Primeiramente a formação de complexos HMW de Tsa1, Tsa2 e mutantes relacionados à superoxidação foram analisados através de SEC. Para obtenção de resultados satisfatórios, foi necessária uma etapa de padronização dos resultados, sendo possível a obtenção de HMW com a utilização de altas concentrações de proteína (1mg/mL ou 43.6 μM) e hidroperóxido (50 mM).

Os resultados dos experimentos demonstraram a formação de HMW para Tsa1 e Tsa2, semelhante aos complexos demonstrados por Jang e colaboradores (2004). Para a proteína Tsa1 são formadas diferentes espécies, que variam de 40 kDa (dímeros), espécies de com cerca de 200 kDa, compatível com formas decaméricas e também espécies HMW com mais de 1000 kDa. Cabe ressaltar, que um grande número de espécies intermediárias também são detectadas (Figura 29A e 29B). Quando o substrato da reação é o H₂O₂ é verificada uma predominância de estruturas decaméricas, mas também são detectadas estruturas de maior peso molecular (Figura 29A, linha vermelha). Já quando o substrato utilizado é o CHP (Figura 29A, linha azul), existe uma diminuição na formação de estruturas com cerca de 200 kDa (decâmero) e ocorre um aumento significativo na formação de HMW.

Para a proteína Tsa2 também foi verificada a formação de HMW, quando o H₂O₂ foi utilizado como substrato, porém em quantidades muito mais modestas quando comparado a Tsa1 (Figura 29B, linha vermelha). Por outro lado quando o substrato da reação foi o CHP também foi verificada a formação de complexos HMW (> 1000 kDa) (Figura 29B, linha azul). Adicionalmente, também é possível destacar que para Tsa2 ocorre a formação de uma quantidade muito menor de estruturas de massas moleculares intermediárias, prevalecendo estruturas de ~200 kDa e estruturas com mais de 1000 kDa.

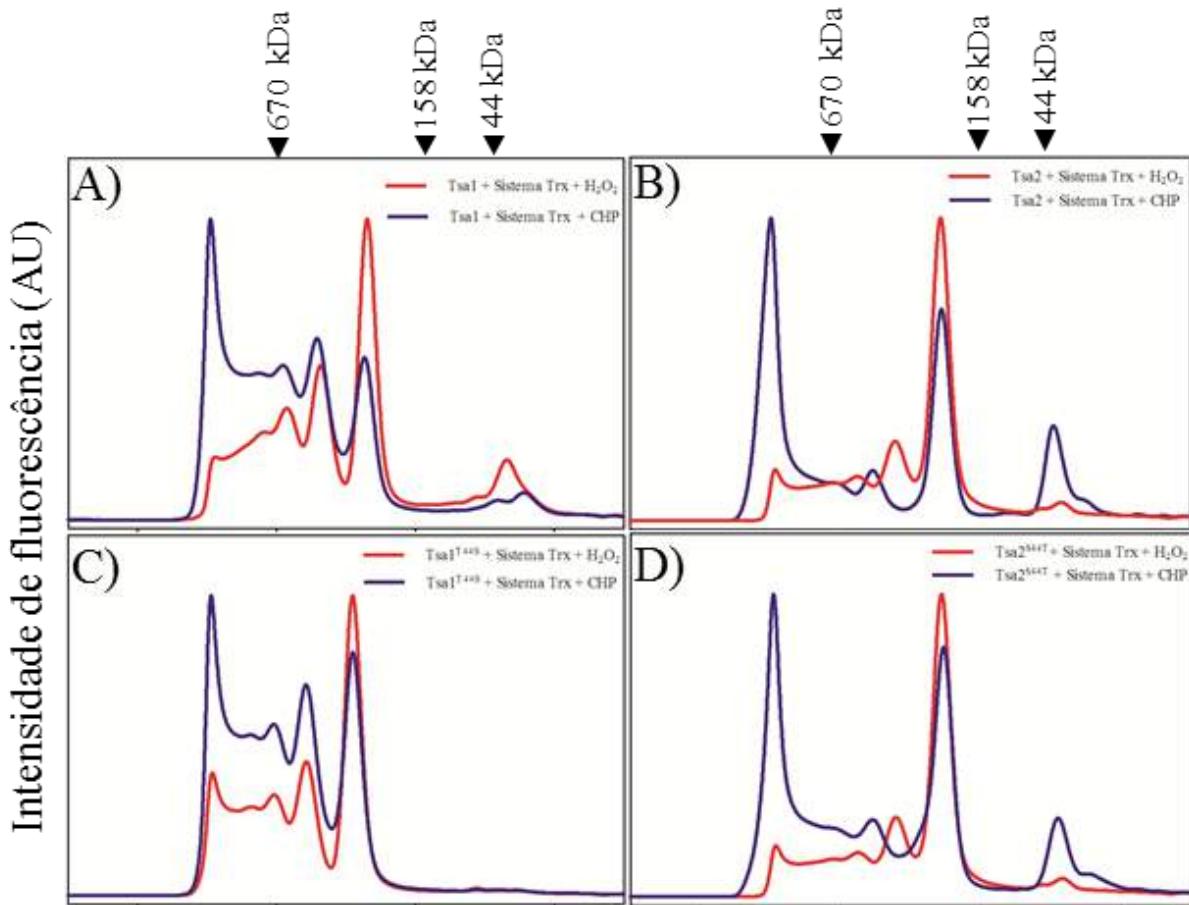

Figura 29. Analise da formação de HMW por SEC. Ensaios contendo Tsa1 (A), Tsa2 (B), Tsa1^{T44S} (C) e Tsa2^{S44T} (D) foram realizados *overnight* em tampão Hepes-NaOH pH 7.0 contendo 100 µM de DTPA, 1 mM de azida, 1 mM de NADPH, 1mg/mL(42.4 µM) de Prx, 1 µM de Trx1, 0.3 µM de TrxR1 e concentrações 50mM de H₂O₂ (linha vermelha) ou 50 mM de CHP (linha azul). Os padrões de peso molecular são representados pelas setas pretas na parte superior dos cromatogramas: tiroglobulina (bovina) (670 kDa), γ-globulina (bovina) (158 kDa) e ovalbumina (frango) (44 kDa). Representações gráficas foram geradas utilizando GraphPad Prism 4.0. Para motivo de comparação dos tempos de retenção, todos os cromatogramas estão normalizados.

A análise dos mutantes Tsa1^{T44S} e Tsa2^{S44T} por outro lado, revela que neste caso os mutantes apresentaram formação de HMW muito semelhantes aos formadas pelas proteínas selvagens (Figura 29C e 29D). Neste contexto, os resultados indicam que apesar do resíduo Thr/Ser da tríade catalítica estar envolvido em maior (Thr) ou menor (Ser) suscetibilidade a superoxidação de C_P, como demonstrado pelos resultados obtidos nos experimentos espectrofluorométricos, de oxidação de NADPH e análises de superoxidação por SDS-PAGE, os dados sugerem que outros fatores estruturais adicionais devem estar relacionados a formação de complexos HMW.

Para uma análise mais aprofundada da formação de complexos HMW foram realizadas análises utilizando microscopia eletrônica de transmissão (TEM). Para as análises de TEM foram realizados ensaios de superoxidação com sistema Trx em altas concentrações de CHP. Em todas as análises de TEM foram testadas diferentes diluições de amostras, até serem

obtidas as melhores imagens (Figura 30). Para a proteína Tsa1 foram observados decâmeros e estruturas esféricas de tamanhos variados, resultados muito semelhantes aos observados por Jang e colaboradores (2004) (Figura 30A). A proteína Tsa2 também apresentou decâmeros e estruturas esféricas com tamanhos variados, mas foi verificada a presença de decâmeros empilhados (Figura 30B), estruturas estas não observadas no trabalho de Jang e colaboradores (2004).

Os resultados dos mutantes $Tsa1^{T44S}$ e $Tsa2^{S44T}$, revelam que $Tsa1^{T44S}$ apresentou estruturas decaméricas e empilhamento de decâmeros e o mutante $Tsa2^{S44T}$ apresentou decâmeros, esferas de tamanhos variados e empilhamento de decâmeros (Figura 30C e 30D).

A formação de diferentes HMW tem sido demonstrada na literatura, Jang e colaboradores (2004) foram os primeiros a demonstrar a formação destas estruturas e as relaciona a atividade de chaperona molecular. Neste trabalho os autores relatam a existência de estruturas semelhantes em Tsa2. À análise dos resultados de TEM obtidos neste trabalho demonstram a formação de estruturas muito semelhantes às observadas por Jang e colaboradores após reações de superoxidação com CHP, inclusive no que se refere ao um tamanho variado das esferas. Por outro lado, foi verificada a formação de estruturas tubulares, ocasionada pelo empilhamento de decâmeros, as quais não foram visualizadas no trabalho pioneiro. Outro fato bastante interessante está relacionado à ocorrência de estruturas diferenciais, Tsa1 apresentou a formação de HMW em forma de esferas e em todo o conjunto de dados e não foi visualizada nenhuma estrutura formada pelo empilhamento de decâmeros. Tsa2 por sua vez, apresentou uma acentuada formação de HMW, sendo verificada a ocorrência de estruturas esféricas e tubulares de tamanhos variados. Já o mutante $Tsa1^{T44S}$ apresentou somente estruturas tubulares, não sendo verificadas estruturas esféricas e finalmente o mutante $Tsa2^{S44T}$ apresentou ocorrência de ambas estruturas, mas a maior parte formada a partir de empilhamento de decâmeros.

De fato decâmeros empilhados já foram observadas em outras 2-Cys Prx, mas não para Tsa1 (Aran *et al.*, 2011; Jang *et al.*, 2004; Kumsta e Jakob, 2009; Saccoccia *et al.*, 2012). Neste contexto essas análises revelam mais uma diferença marcante entre estas duas proteínas, apesar de diferenças funcionais relacionadas a estas estruturas de alto peso molecular, ainda não serem compreendidas.

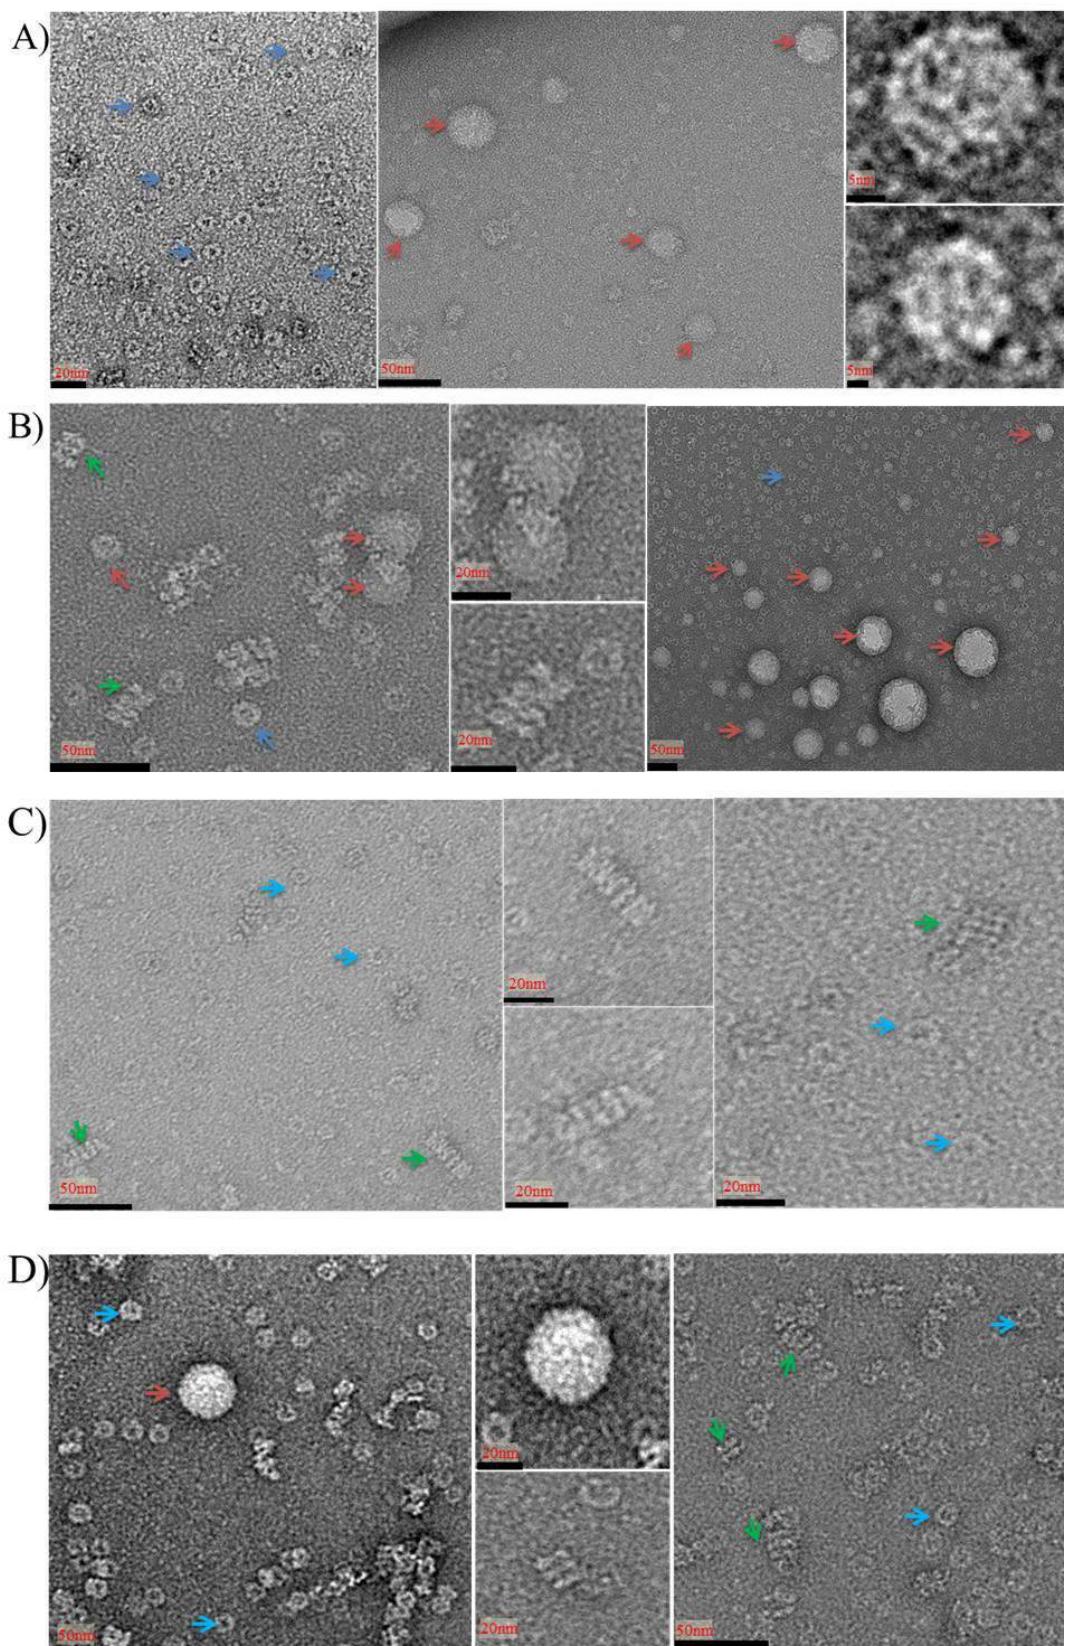

Figura 30. Resultado de TEM de amostras de Tsa1 e Tsa2, Tsa1^{T44S} e Tsa2^{S44T} superoxidadas. Análise de HMW de Tsa1 (A) e Tsa2 (B) Tsa1^{T44S} (C) e Tsa2^{S44T} (D) após reação com sistema Trx em altas concentrações de CHP. Ensaios para formação de espécies superoxidadas de Tsa1, foram realizados *overnight* a 4°C em tampão Hepes-NaOH 50 mM pH 7.4 contendo 100 µM de DTPA, 1 mM de azida, 600 µM de NADPH, 9.3 µM de Prx, 1 µM de Trx1, 0.3 µM de TrxR1 e concentração 10 mM de CHP. Após a reação as amostras foram filtradas em filtro Millex 0.22 µM (Millipore) e diluídas em concentrações variáveis até serem obtidas as melhores imagens.

As imagens de TEM foram adquiridas utilizando microscópio eletrônico de transmissão Jeol JEM-2100 operado a 200 kV e equipado com câmera F-416 CMOS (Tietz Video and Image Processing Systems). A escala em cada imagem. Setas azuis representam estruturas decaméricas, setas vermelhas estruturas esféricas de alto peso molecular e setas verdes representam a decâmeros empilhados.

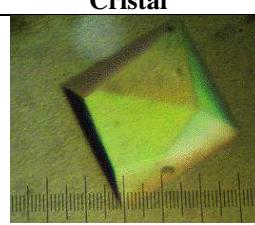

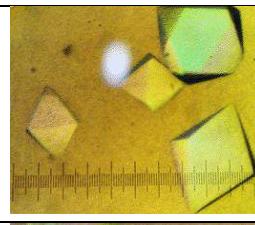

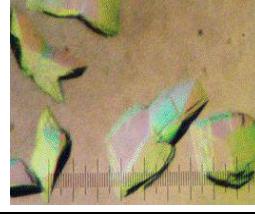

5.4 CAPÍTULO 4 - Cristalização de Tsa2 e Obtenção de Modelo por SAXS

5.4.1 Cristalização de Tsa2 e Tsa2^{C47S}

Como pode ser observado ao longo da tese, encontramos diferenças funcionais e estruturais significativas entre Tsa1 e Tsa2. Uma vez que peculiaridades nas estruturas destas proteínas devem responder pelas diferenças observadas e a estrutura cristalográfica de Tsa1 foi determinada por nosso grupo de pesquisa (Oliveira, de *et al.*, 2007; Tairum *et al.*, 2012), também foi objetivo deste doutoramento a determinação da estrutura de Tsa2.

Inicialmente foram realizados experimentos de triagem de condições de cristalização da proteína reduzida por DTT ou oxidada com H₂O₂ ou CHP (seção Materiais e Métodos) e após a obtenção dos microcristais foram realizados experimentos de refinamento das condições de cristalização mais promissoras, variando a concentração de precipitante, sais e pH. Várias tentativas de obter cristais passíveis de difração foram realizados, mas infelizmente não foram obtidos cristais com difração suficiente para resolver a estrutura de Tsa2. Alguns cristais obtidos são apresentados na Tabela 4. De todos os cristais obtidos poucos apresentaram difração, sendo a melhor difração obtida a 3.7 Å (Figura 31).

Tabela 4. Refinamento de cristalização da condição 0.1 M Acetato de sódio trihidratado pH 4.0 e 8% PEG 8000.

	Condição	Tratamento	Cristal
Tampão	0.1 M Acetato de sódio trihidratado pH 4.0		
Precipitante	6% de PEG 4000	1 mM H ₂ O ₂	
Sal	-		
Tampão	0.1 M Acetato de sódio trihidratado pH 5.6		
Precipitante	10% de PEG 4000	1 mM H ₂ O ₂	
Sal	-		
Tampão	0.1M Acetato de sódio trihidratado pH 3.6		
Precipitante	12% PEG 4000	1 mM H ₂ O ₂	
Sal	-		

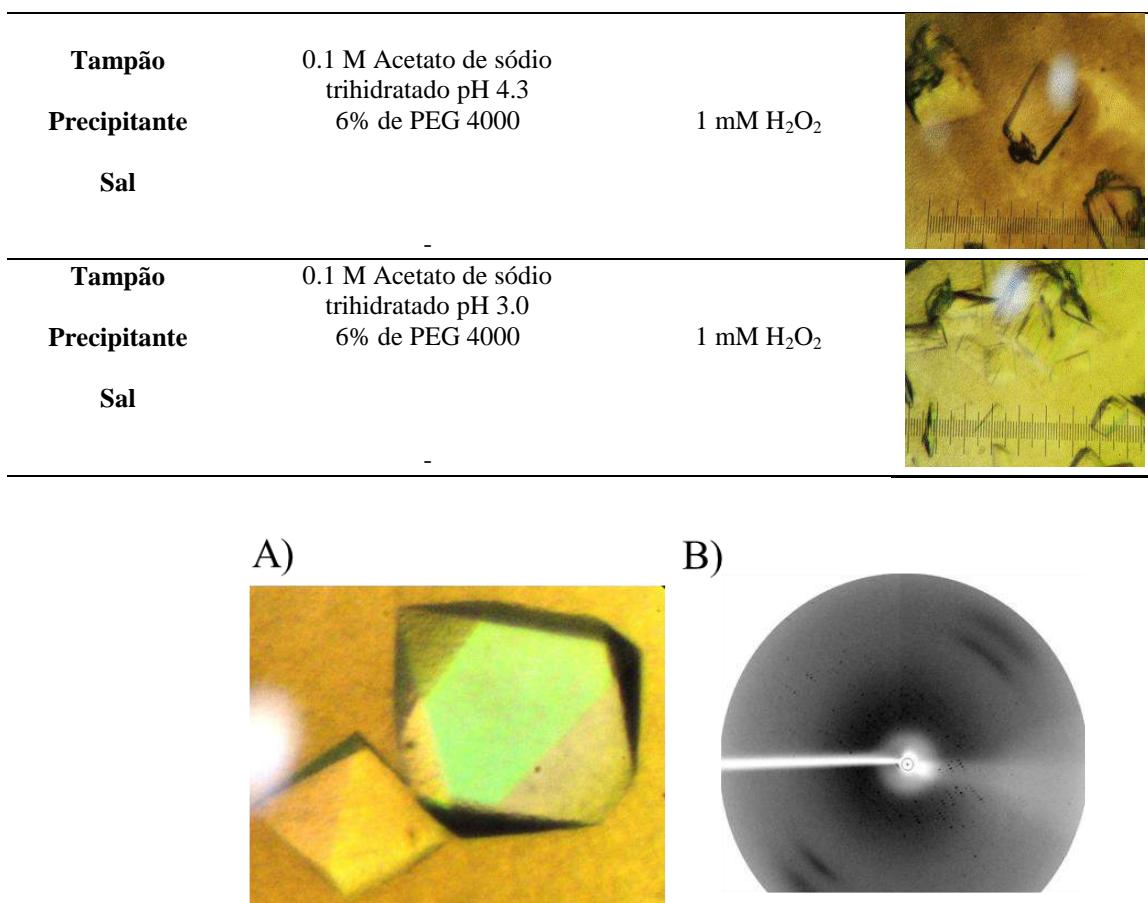

Figura 31. Cristais e difração dos cristais de Tsa2. A) Cristais de Tsa2 obtidos através do método de gota pendurada nas condições de acetato de sódio trihidratado 0.1 M pH 5.6 e 10% de PEG 4000. B) Padrão de dispersão registrado pela placa de imagem MARCCD. Os cristais foram crioprotectados com glicerol (20%) e submetidos à difração de raio-X da linha de luz DB03-MX1. A melhor difração obtida foi a 3.7Å.

Uma vez que todas as tentativas de obtenção de cristais passíveis de difração da proteína Tsa2 selvagem não geraram resultados satisfatórios, foram efetuadas uma série de triagens utilizando o mutante Tsa2^{C47S}, o qual carrega a substituição da C_P por uma serina. Cabe ressaltar que esta abordagem foi adotada anteriormente com Tsa1, no qual apesar de inúmeras abordagens a proteína selvagem não formou cristais passíveis de difração, e com a substituição de C_P por Ser foi possível a determinação da estrutura (Oliveira, de *et al.*, 2007; Tairum *et al.*, 2012).

Como efetuado para a proteína Tsa2 selvagem, as condições em que apareceram microcristais, foram refinadas (concentração de proteína, sal, precipitante e pH), entretanto todos os cristais obtidos se apresentaram muito frágeis, dificultando muito os experimentos de difração, e difratando em baixa resolução (>7Å). Ainda com intuito de resolver a estrutura da proteína Tsa2 foi realizado um estágio no Laboratório de Biologia Estrutural de Proteínas no Centro de Investigaciones Biologicas (Madrid/Espanha) sob supervisão do Dr. Francisco Javier Medrano Martin.

Para a realização dos experimentos inicialmente foram realizadas otimizações nos protocolos de expressão e purificação das proteínas para a obtenção de altas concentrações proteicas com alto nível de pureza de uma forma rápida. Diferentemente dos experimentos realizados anteriormente foi optado pela retirada da HIS-Tag das proteínas Tsa2 e Tsa2^{C47S}. A retirada da HIS-Tag destas proteínas foi realizada utilizando a protease 3C (*Human rhinovirus 3C protease*) a qual reconhece o sítio Leu-Glu-Val-Leu-Phe-Gln-Gly-Pro que está localizado entre a HIS-Tag e o códon de iniciação da proteína (Met). A possibilidade dessa digestão ocorreu, pois as proteínas foram expressas utilizando o plasmídeo pEPEROEX-HT o qual insere o sítio reconhecido pela 3C protease.

Apesar dos cristais obtidos não apresentarem um padrão considerado ideal para experimentos de difração foram realizados refinamentos de todas as condições obtidas, sendo variados nos refinamentos o pH e a concentração de precipitante. Em condições que apresentavam duas soluções precipitantes foram testadas diferentes combinações destas soluções. Os melhores cristais obtidos são apresentados na tabela 5. Apesar de todas as proteínas testadas terem cristalizado em no mínimo uma condição testada, só foram obtidos cristais com boa formação para a proteína Tsa2.

Experimentos de difração de cristais foram realizados na linha BL13 do ALBA Synchrotron (Barcelona/Espanha). Infelizmente os cristais obtidos para a proteína Tsa2 não apresentaram difração, possivelmente por apresentarem uma alta desorganização interna, que não permite a difração.

Tabela 5. Refinamento das condições de cristalização das proteína Tsa2 realizadas no Laboratório de Biología Estrutural de Proteínas no Centro de Investigaciones Biológicas (Madrid/Espanha)

	Condição	Proteína e Tratamento	Cristal
Tampão	0.1 M Fosfato de sódio e potássio pH6.2		
Precipitante	10% PEG 800	Tsa2	
Sal	0.2 M de NaCl	10 mM H2O2	
Tampão	-		
Precipitante	15% PEG 8000	Tsa2	
Sal	0.5 M Sulfato de lítio	10 mM H2O2	

Tampão		
Precipitante	15% PEG 8000	Tsa2
Sal	0.5 M Sulfato de lítio	10 mM DTT

5.4.2 Análise estrutural de Tsa2 utilizando SAXS

Uma vez que não foi possível estabelecer condições para cristalização e determinar a estrutura de Tsa2, optamos por fazer a análise estrutural de Tsa2, reduzida e oxidada, através de experimentos de SAXS utilizando a Linha B21 do *Diamond Light Souce*, Oxfordshire, Inglaterra. Infelizmente, só foi possível obter o modelo estrutural da proteína Tsa2 na forma reduzida, os dados das outras amostras apresentaram padrões de qualidade baixos não permitindo a obtenção de modelos confiáveis. Para a obtenção do modelo, a proteína Tsa2 foi previamente reduzida com 10 mM de DTT e foram realizados experimentos com diferentes concentrações proteicas e os melhores resultados foram obtidos com concentração de 10 mg/mL. Após a coleta dos dados de SAXS a subtração do tampão foi realizada utilizando o programa ScÅtter (<http://www.bioisis.net/>).

A análise dos dados demonstra que Tsa2 apresenta estrutura muito semelhante a Tsa1, a análise comparativa dos dados experimentais de SAXS e a da curva teórica gerada com base na estrutura de Tsa1 (PDB 3SBC) pelo servidor FOXS (<http://modbase.compbio.ucsf.edu/foxs/index.html>) demonstra essa semelhança (Figura 32A). A análise de Kratky demonstrou que a proteína se apresentava bem enovelada no momento dos experimentos, sem agregados e regiões desenoveladas (Figura 32B) (Putnam *et al.*, 2007). O cálculo da P_r e D_{max} foi realizado utilizando o programa PRIMUSqt (Konarev *et al.*, 2003) e os modelos foram gerados utilizando o programa DAMMIF *online* (Franke e Svergun, 2009).

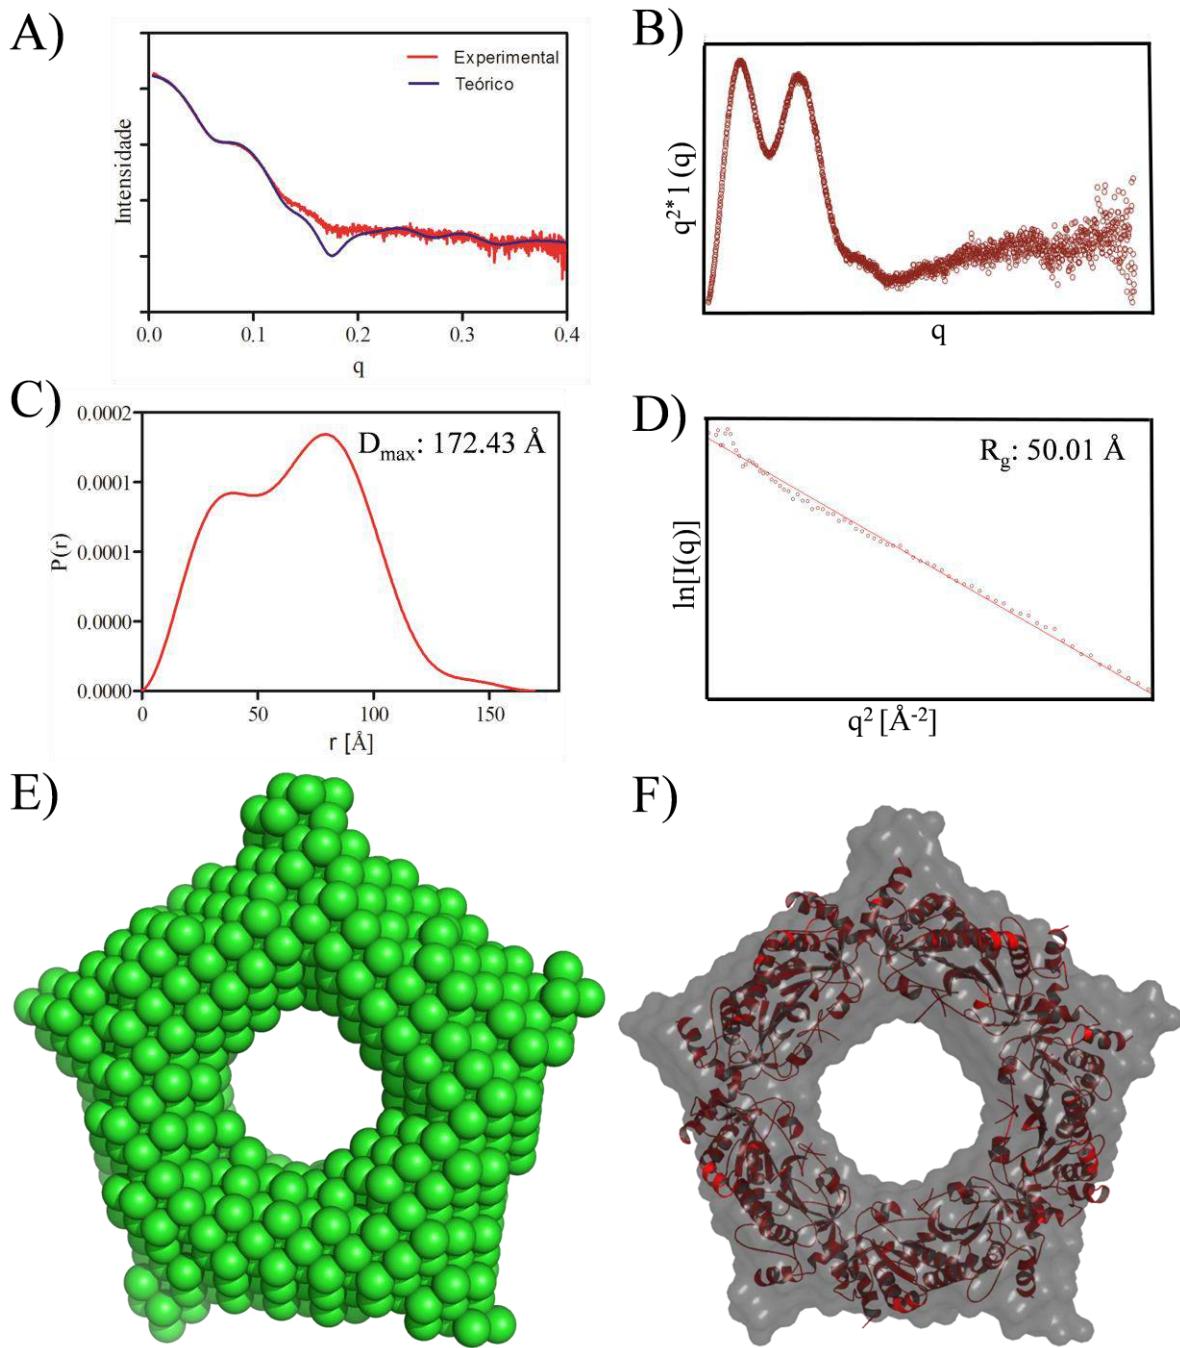

Figura 32. Modelo estrutural de Tsa2 obtido através de SAXS. A) Comparação dos dados experimentais de Tsa2 com a curva teórica de Tsa1. A comparação dos dados foi realizada utilizando o servidor FOXS (<http://modbase.compbio.ucsf.edu/foxs/index.html>) (Schneidman-Duhovny, Hammel e Sali, 2010; Schneidman-Duhovny *et al.*, 2013). B) A análise de Kratky foi realizada utilizando o programa Primusqt (Konarev *et al.*, 2003). C) Análise da $P(r)$ do modelo de Tsa2, realizado utilizando o programa Primusqt (Konarev *et al.*, 2003). D) Análise de Guinier de Tsa2 realizada através do programa Primusqt (Konarev *et al.*, 2003). E) Modelo de Tsa2 obtido através do programa DAMMIF *online* (Franke e Svergun, 2009). F) Alinhamento do modelo de SAXS de Tsa2 com a estrutura de Tsa1 (PDB:3SBC), alinhamento realizado com o programa SUPCOMB (Kozin e Svergun, 2001b). As imagens das figuras E e F foram geradas através do programa PyMOL.

A tabela 6 demonstra os valores experimentais de SAXS de Tsa2 em comparações a valores teóricos obtidos a partir da estrutura de Tsa1 (PDB: 3SBC).

Tabela 6. Valores Experimentais do Modelo de Tsa2

	Tsa2 (SAXS)	Tsa1 (3SBC)
R_g (Å)	51.28	-
R_g (Å) real	51.25	49.83
D_{max} (Å)	172.43	137
V_{Porod} (Å³)	320231	-
Massa (kDa)	200.14	216

* Comparação dos dados de SAXS de Tsa2 com dados teóricos baseados estrutura da proteína Tsa1.

O modelo da proteína Tsa2 foi obtido através do programa DAMMIF *online* (<http://www.embl-hamburg.de/biosaxs/atsas-online/DAMMIF>), para a obtenção do modelo final foram gerados 20 modelos, para facilitar a obtenção dos modelos, foi imposto o grupo espacial P5 e simetria oblata. O NSD obtido foi de 0.663 com uma variação de 0.451, sendo utilizando para a geração do modelo final 19 modelos (Figura 32E). Para uma análise comparativa o modelo obtido foi alinhado com a estrutura de Tsa1 utilizando o programa SUPCOMB (Kozin e Svergun, 2001b), o resultado do alinhamento é apresentado na figura 32F e demonstra grande similaridade com a estrutura de Tsa1.

5.5 CAPÍTULO 5 - Importância da Thr44 na atividade e estabilização do decâmero de Tsa1

Adicionalmente a investigação conduzida, também participei da investigação do papel da Thr⁴⁴ e da Arg¹²³ de Tsa1 na reatividade sobre hidroperóxidos e manutenção do decâmero (Apêndice A - Manuscrito em fase final de elaboração que será submetido ao periódico *Nature Chemistry Biology*). Neste trabalho uma análise aprofundada da estrutura demonstrou que o C γ da Thr⁴⁴ atua como um doador de hidrogênio para o sistema π da Tyr⁷⁷ (Apêndice A, Figura 2). Este tipo de ligação é considerada uma ligação de hidrogênio não clássica, denominada de CH- π e vem apresentando um papel muito importante na estrutura e função de uma série de proteínas (Brandl *et al.*, 2001). De fato, a distância entre o C γ da Thr⁴⁴ e o centroide da Tyr77 (3.30 - 3.68 Å) e o ângulo da ligação (113.23 - 134.40°) ficam dentro dos parâmetros teóricos determinados para esse tipo de interação (Apêndice A, Figura 3A) (Brandl *et al.*, 2001).

A avaliação de diferentes estruturas de 2-Cys Prx nos estados FF e LU demonstra que essa ligação é conservada (Apêndice A, Figura 3), sendo que em alguns casos a Tyr⁷⁷ é substituída por uma Phe, que também é capaz de realizar uma ligação CH- π com a Thr (Apêndice A, Figura S1). Vale ressaltar que quando as enzimas apresenta-se no estado LU, ocorrem modificações significativas no posicionamento do C γ da Thr⁴⁴ o que nos levou a postular que está mudança estaria relacionada com a transição dímero → decâmero (Apêndice A, Figura 3). De acordo com as análises realizadas, a Thr⁴⁴ possui envolvimento na estabilização do decâmero através da CH- π com Tyr⁷⁷ e atividade através do átomo de O γ que possui interações polares com o S γ da C_P, que é estabilizada através de interações polares com o grupo guanidina da Arg¹²³. Tendo em vista as análises realizadas postulamos que a substituição da Thr⁴⁴ por outros aminoácidos pode desestabilizar a ligação CH- π afetando a estabilidade do decâmero e também a atividade da enzima. Para investigar estes aspectos, foram geradas substituições de Thr⁴⁴ por Ala, Ser, Val e Arg¹²³ por Lys e Gly e análises estruturais utilizando cromatografia de exclusão molecular (SEC) foram realizadas (Apêndice A, Figura 4). Em condições redutoras Tsa1, Tsa1^{T44A} e Tsa1^{T44S} apresentam estruturas decaméricas (Apêndice A, Figura 4A, 4B e 4C, linhas sólidas), já Tsa1^{T44V} apresenta uma mistura de dímeros e decâmeros, sendo que ocorre uma predominância de estruturas diméricas (Apêndice A, Figura 4D, linhas sólidas). Na forma oxidada (dissulfeto) ocorre um aumento da formação de estruturas diméricas (Apêndice A, Figura 4, linhas pontilhadas) com exceção da proteína Tsa1^{T44S} que apresentou apenas estruturas decaméricas, e Tsa1^{T44V} que

apresentou majoritariamente estruturas diméricas. Com relação às mutações na Arg¹²³ as mudanças estruturais foram bem menos significantes, e se apresentam com estrutura quaternária similar a Tsa1 selvagem (Apêndice A, Figura 4E e 4F).

Ensaios de atividade por meio de cinética de estado estacionário, utilizando ensaio de NADPH e determinação de constantes de pseudo-primeira ordem, revelaram que enquanto Tsa1^{T44S} apresentou parâmetros cinéticos similares a da enzima selvagem e Tsa1^{T44A} uma moderada redução na atividade, Tsa1^{T44V} apresentou atividade peroxidásica altamente comprometida (Apêndice A, Figura 5, Tabela 1). No caso dos mutantes Tsa1^{R123G} e Tsa1^{R123K} foi verificada apenas uma atividade residual, dados esses já demonstrados na literatura para outras 2-Cys Prx típicas (Flohé *et al.*, 2002; Montemartini *et al.*, 1999; Portillo-Ledesma *et al.*, 2014).

Para um maior entendimento da importância da ligação CH-π foi gerado o mutante Tsa1^{Y77A} e em seguida avaliamos a atividade e o grau oligomérico deste mutante bem como de Tsa2 o qual apresenta a substituição natural de Thr⁴⁴ por uma Ser. Análises de SEC demonstram que Tsa2 migra exclusivamente em decâmeros, independente do estado redox da enzima, resultado semelhante ao observado no mutante Tsa1^{T44S} (Apêndice A, Figura 9A). Em contraste Tsa1^{Y77A} apresentou somente estrutura dimérica, demonstrando que a interação CH-π apresenta grande importância na manutenção da estrutura decamérica (Apêndice A, Figura 9B). De fato, análises de modelos contendo as substituições de Thr estudadas no trabalho indicam que as substituições devem influenciar de forma significativa a rede de interações polares existente entre os resíduos da tríade catalítica (Figura 33).

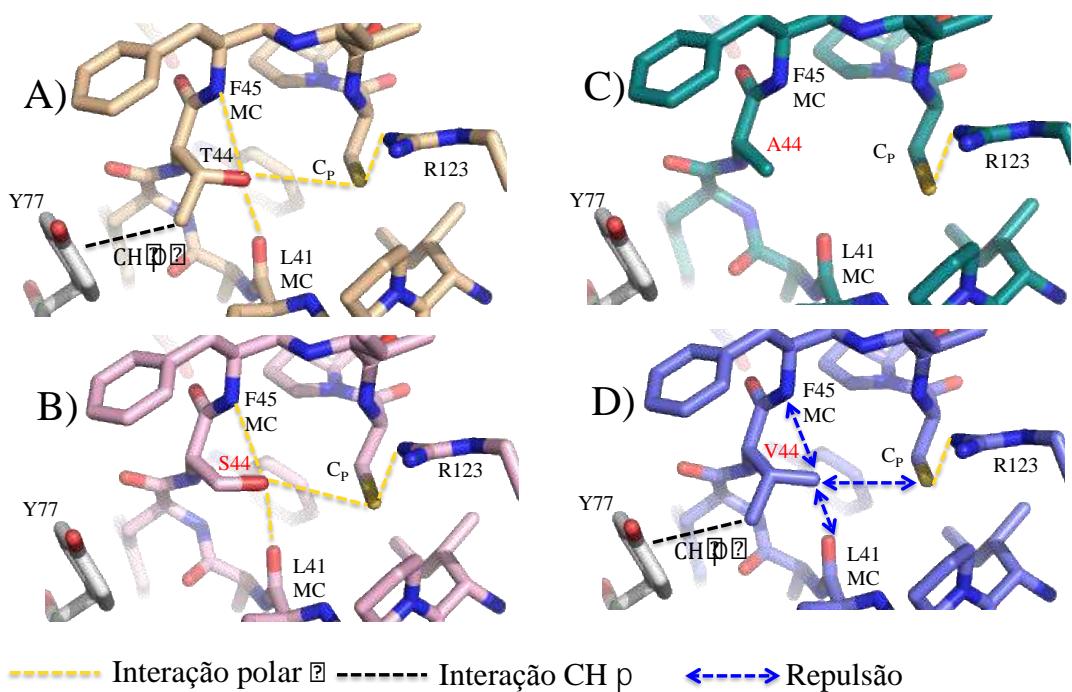

Figura 33. Efeitos teóricos da substituição de Thr sobre interações moleculares no sitio ativo de Tsa1. (A) Tsa1 representado *sticks* evidenciando as interações polares (linha tracejada amarela) e CH---π (linha tracejada amarela). (B) Tsa1^{T44A}; (C) Tsa1^{T44S} e (D) Tsa1^{T44V}, a linha contendo a dupla seta em azul denota repulsão. Os modelos teóricos foram criados utilizando o programa WINCOOT, utilizando a estrutura de Tsa1 (3SBC), a substituição foi realizada mantendo a mesma posição da Thr.

Conjuntamente, nossos resultados demonstraram de forma sistemática a importância da ligação CH-π entre a Thr da tríade catalítica e a Tyr do dímero adjacente para a manutenção do decâmero e atividade peroxidásica máxima de Tsa1. Os resultados compõem um manuscrito em fase final de elaboração que será submetido ao *Nature Chemical Biology* (Apêndice A).

Como pode ser constatado na figura 33, assunto que não foi abordado no manuscrito, o resíduo seja de Thr ou Ser é capaz de estabelecer ligações polares com o grupo amina de Phe⁴⁵ e o grupo carboxila da Leu⁴¹. Cabe ressaltar que estas interações foram detectadas em todos os sítios ativos analisados de Tsa1, o que nos parece importante uma vez que até o presente momento estas interações não foram levadas em consideração na literatura. Cabe ressaltar que a análise de enzimas 2-Cys Prx típicas no estado oxidado em dissulfeto (LU) revela que estas interações são desfeitas.

Para avaliar a importância destas interações foram analisadas todas as estruturas em FF (estado reduzido) presentes no banco de dados pdb. De fato como pode ser observado na figura 34 estas interações são conservadas entre as estruturas. A análise das distâncias do O_λ de Thr⁴⁴ para O da cadeia principal do resíduo de Leu (substituído por Ala em enzimas de procariotos) é invariavelmente abaixo de 3 Å, enquanto que para o N da Phe, conservado entre

eucariotos e procariotos, varia de 3-4 Å, que representa sempre uma distância similar ao S_λ da cisteína peroxidásica. Para uma melhor compreensão calculamos as distâncias médias das interações polares entre os resíduos (Tabela 7). Neste contexto, estas análises incluem um pouco mais de complexidade e propõe a participação do $O\gamma$ da Thr da tríade catalítica na estabilização do tiolato de C_P .

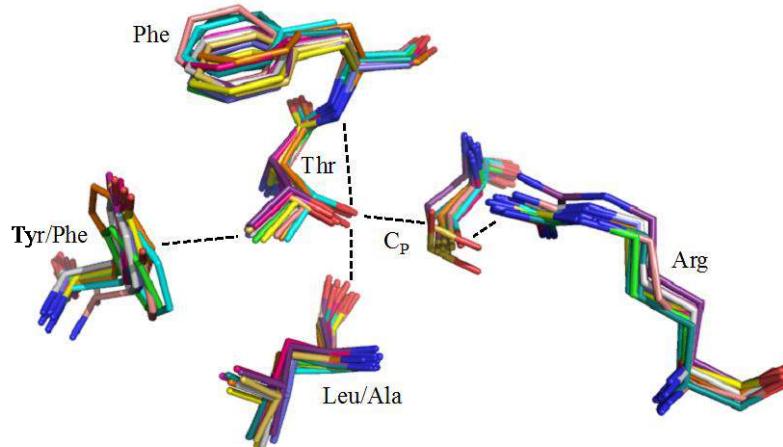

Figura 34. Sobreposição de estruturas de 2-Cys Prx típicas no estado FF revelando a rede de interações polares entre aminoácidos do sítio ativo. Estruturas de 2-Cys Prx típicas no estado FF e coloridas CPK: O: vermelho; S: laranja; N: Azul. A cor dos carbonos diferem as estruturas analisadas: verde (4MA9); azul claro (1N8J); cereja (4K1F); amarelo (2I81); rosa claro (3ZTL); cinza (3QMP); azul claro (3TKR); laranja (2Z9S); azul celeste (1QMV); azul ardósia (3SBC); caqui (3TKP) e ametista (3TKS).

Os resultados das análises sugerem que o resíduo de Thr não deve estar somente relacionado com a manutenção de C_P em S⁻, mas que estes resíduos poderiam estar relacionados com o direcionamento do hidroperóxido para o tiolato, para a formação do complexo de transição e proporcionar o mecanismo de substituição nucleofílica do tipo SN2 conforme proposto por Hall e colaboradores (2010). Neste contexto, as interações polares efetuadas entre os átomos da cadeia principal de Leu e Phe inicialmente manteriam e criariam um ambiente carregado positivamente. Essa ambiente permitiria a entrada do hidroperóxido, em um segundo momento o oxigênio distal da molécula do hidroperóxido seria estabilizado por interações polares com hidrogênios oriundos do grupo amino de Phe⁴⁵ e do Oγ da Thr44. O oxigênio proximal do hidroperóxido seria positivado por um hidrogênio do grupo amino da Arg123, o que permitiria o ataque do tiolato sobre a ligação O-O do hidroperóxido, com a formação de cisteína acido sulfênico (C_P-SOH) e liberação do grupo abandonador (OH⁻). Esse processo desencadearia o desenovelamento da alfa hélice e transição do estado FF→LU, com consequente disruptão do decâmero (Figura 35).

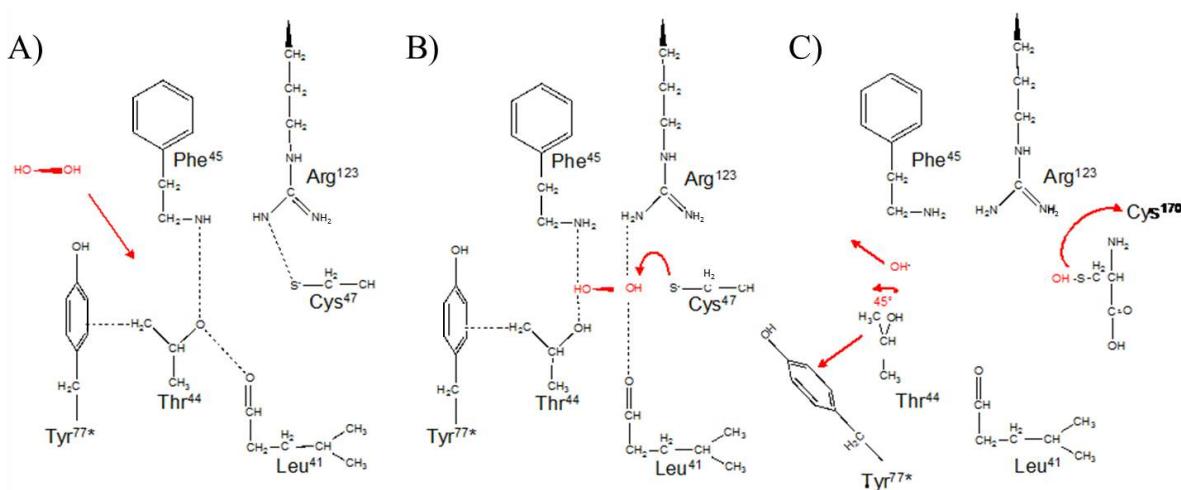

Figura 35. Mecanismos proposto para a estabilização do hidroperóxido e formação do complexo de transição de 2-Cys Prx típicas. A) Leu e Phe incialmente mantem e criam um ambiente carregado positivamente para permitir a entrada do hidroperóxido. B) Em um segundo momento o oxigênio distal da molécula do hidroperóxido seria estabilizado por interações polares com hidrogênios oriundos do grupo amino de Phe⁴⁵ e do O_γ da Thr44, enquanto que o oxigênio proximal do hidroperóxido seria positivado por um hidrogênio do grupo amino da Arg123. C) Ocorre ataque do tiolato sobre a ligação O-O do hidroperóxido, com a formação de cisteína acido sulfênico (C_P-SOH) e liberação do grupo abandonador (OH⁻) que desencadearia o desenovelamento da alfa hélice e transição do estado FF→LU.

Entretanto, este mecanismo precisa ser investigado de forma mais consistente. De fato, a utilização de mutantes esbarra no fato de que as interações propostas de Phe e Leu são efetuadas por átomos da cadeia principal. Uma abordagem seria a substituição de Phe45 e a Leu41 por uma Pro, com o intuito de afetar o posicionamento da cadeia principal destes aminoácidos. No caso da Leu uma substituição adequada poderia ser por Asp, pois a cadeia lateral da Leu estabelece interações de caráter apolar com aminoácidos vicinais e uma alteração desta natureza deve também perturbar a posição de sua cadeia principal.

6 CONSIDERAÇÕES FINAIS

Este trabalho teve por objetivo uma análise detalhada da redundância de duas 2-Cys Prx de *S. cerevisiae*, Tsa1 e Tsa2, a qual é proposta por alguns autores (Chae, Kim e Gene, 1993; Netto *et al.*, 2007; Ross *et al.*, 2000). Portanto, neste trabalho foram realizadas análises comparativas das proteínas Tsa1 e Tsa2 com relação à atividade sobre seus substratos redutores e oxidantes e relações com a superoxidação de C_P levando em conta ambos os substratos. Estes aspectos também foram relacionados com transições estruturais que levam a formação de complexos de alto peso molecular (HMW) em 2-Cys Prx como consequência da superoxidação de C_P.

Através de experimentos envolvendo consumo de NADPH demonstramos que Tsa1 e Tsa2 possuem uma alta atividade tanto para H₂O₂ quanto para peróxidos orgânicos (CHP e *t*-BOOH) e ambas são reduzidas com a mesma eficiência tanto por Trx1 quanto por Trx2. Cabe ressaltar que este tipo de abordagem não havia sido efetuado de forma comparativa apesar destas proteínas serem largamente estudadas (Park *et al.*, 2000; Watzlawik *et al.*, 2006). Também constatamos que altas concentrações de peróxido orgânico, em especial o CHP, quando comparado com H₂O₂ leva a uma acentuada inibição no consumo de NADPH o que sugeriu fortemente a superoxidação da C_P a C_PSO_{2/3}. Para investigar este aspecto foram efetuados ensaios de consumo de NADPH com quantidades variáveis de peróxidos e a detecção das formas oligoméricas foi efetuada por meio de SDS-PAGE, conforme metodologia descrita anteriormente (Nelson *et al.*, 2013; Perkins *et al.*, 2013). Os resultados demonstraram que a inibição observada nos ensaios de consumo de NADPH é causado pela superoxidação de C_P a C_PSO_{2/3}, e também confirmaram que Tsa2 apresenta-se muito mais resistente a superoxidação quando comparada a Tsa1.

Adicionalmente, foram efetuadas análises cinéticas de fluorescência, método pelo qual foi possível detectar a superoxidação de outra classe de peroxirredoxina (AhpE) de *Mycobacterium tuberculosis* (Reyes *et al.*, 2011), que revelaram que mesmo pequenas doses de hidroperóxidos são capazes de superoxidar Tsa1. Entretanto, nas condições testadas não foi possível detectar a superoxidação de Tsa2, o que confirma os resultados obtidos por oxidação de NADPH e observados também em SDS PAGE.

Entretanto, os dados dos ensaios fluorométricos foram bastante contrastantes com os obtidos por cinética de estado estacionário. De fato nos experimentos envolvendo fluorometria foram utilizadas doses muito menores de hidroperóxidos (máximo de 10 equivalentes molares) que nos ensaios de cinética estacionária de oxidação de NADPH

utilizando o sistema Trx, onde a indícios de superoxidação de Tsa1 só foi detectada em altas concentrações de hidroperóxidos (50-500 eq.). Neste contexto, os dados de fluorescência devem indicar que somente uma pequena parcela das proteínas deveria ser responsável pelo aumento de fluorescência detectado. Para investigar este aspecto, primeiramente foram feitas análises de SDS PAGE de Tsa1 e Tsa2 tratadas com altas quantidades de hidroperóxidos (100 eq), entretanto não foi possível observar qualquer indício de superoxidação.

As diferenças de suscetibilidade/resistência foram então investigadas em função do ambiente do sitio ativo. De fato, a diferença mais marcante reside na substituição de um resíduo de Thr de Tsa1 por uma Ser em Tsa2, que podem realizar interações polares similares, mas não idênticas no sitio ativo. Para investigar a influencia desta substituição foram utilizados mutantes carreando substituições reciprocas ($Tsa1^{T44S}$ e $Tsa2^{S44T}$). Os resultados revelaram que esta única substituição foi capaz de conferir alta resistência a superoxidação por CHP para $Tsa1^{T44S}$ e aumentar a sensibilidade de forma significativa para $Tsa2^{S44T}$, demonstrando a importância deste aminoácido para a resistência e suscetibilidade ao processo de superoxidação.

Analises da sequencia de aminoácidos de diversas 2-Cys Prx revelaram que esta substituição de Thr-Ser só é compartilhada por um único organismo eucariótico (*Harpegnathos saltator*) sendo que as demais são só detectadas para Prx 2-Cys de bactérias, o que deve indicar uma maior necessidade de enzimas mais resistentes a superoxidação nestes organismos.

Por fim também investigamos a formação de espécies HMW em resposta a processos hiperoxidativos por cromatografia de exclusão molecular e microscopia eletrônica de transmissão. Os resultados de SEC revelaram que as espécies HMW formadas entre Tsa1 e Tsa2, não são idênticas uma vez que Tsa1 possui diversas espécies intermediarias entre decâmeros e complexos HMW. Entretanto, por esta abordagem não foi possível detectar diferenças significativas no perfil cromatográfico de $Tsa1^{T44S}$ e $Tsa2^{S44T}$ quando comparadas com as proteínas selvagens. Por outro lado, quando as enzimas foram avaliadas por TEM foi possível demonstrar que enquanto Tsa1 forma estruturas HMW esféricas de tamanhos distintos, Tsa2 não apresenta somente estruturas esféricas, mas também empilhamento de estruturas toróides decaméricas. Em contraste com os resultados de SEC foi possível observar por TEM que a substituição reciproca do resíduo de Thr/Ser, surtiu efeitos na estrutura de complexos de alto peso molecular, uma vez que foram detectadas estruturas esféricas para $Tsa2^{S44T}$ e em $Tsa1^{T44S}$ foram detectadas estruturas toróides decaméricas.

Conjuntamente nossos resultados revelam que Tsa1 e Tsa2 diferem fortemente no que concerne a suscetibilidade a superoxidação de C_P, a qual é fortemente dependente de Trx, e também na formam estruturas HMW, distintas. Sendo que em ambos os processos a presença do resíduo de Thr/Ser esta fortemente envolvida. Portanto, nossos resultados demostram de maneira clara que Tsa1 e Tsa2 não são proteínas redundantes e que apesar das semelhanças na estrutura primária elas podem apresentar funções distintas ou complementares na célula.

7 PERSPECTIVAS

1. Determinação das constantes de superoxidação para H₂O₂ e CHP utilizando fluorescência intrínseca do triptofano.

Como demonstrado nesta tese a análise da fluorescência intrínseca do triptofano apresenta-se como uma importante metodologia para determinação de constantes de superoxidação. Neste contexto nos parece de grande importância a determinação das constantes de superoxidação de C_P de Tsa2, Tsa1^{T44S} e Tsa2^{S44T}. Esses resultados são fundamentais para a finalização do manuscrito do manuscrito que compreenderá os resultados obtidos nesta tese.

2. Determinação da estrutura de HMW de Tsa1 e Tsa2 utilizando Crio-Microscopia de eletrônica de transmissão

O entendimento das transições estruturais para formação de HMW ainda é muito pouco compreendido, foi demonstrado aqui que o processo de superoxidação é fundamental para a transição de LMW para HMW. Um ponto que inviabilizou a determinação de estruturas HMW por Crio-TEM foi a grande heterogeneidade das amostras, sendo visualizados em nossos experimentos de *negative stain* diversas formas variando de dímeros a estruturas de ~1000 kDa. Tendo em vista essa heterogeneidade é muito difícil a obtenção de uma reconstrução molecular, por outro lado trabalhos presentes na literatura que realizaram reconstruções de HMW de peroxirredoxinas estabilizaram estes complexos através da acidificação do meio onde a proteína está contida. Segundo esses autores, condições ácidas mimetizam a superoxidação da C_P de forma homogênea proporcionando a obtenção de estruturas perfeitas análises por Crio-TEM (Radjainia *et al.*, 2015; Saccoccia *et al.*, 2012).

3. Determinação da estrutura de Tsa2

Apesar das diversas abordagens utilizadas para obter a estrutura de Tsa2, não foi possível a obtenção de cristais passíveis de difração. Apesar das dificuldades encontradas para obtenção desta estrutura novas abordagens ainda são válidas pois a estrutura da proteína Tsa2 poderia explicar em detalhes as diferenças com Tsa1 relacionadas a estrutura e reatividade. Assim novos experimentos de cristalização utilizando diferentes abordagens tais como proteólise limitada e etapas adicionais de cromatografia para preparo de amostras podem viabilizar a obtenção de cristais passíveis de difração.

4- Determinação das constantes de reatividade de Tsa1 e Tsa2 com peróxidos orgânicos naturais

Um ponto importante a ser destacado é que os hidroperóxidos orgânicos *t*-BOOH e CHP são hidroperóxidos sintéticos, não sendo encontrados naturalmente nos orgânicos. Assim seria de grande importância a determinação de constantes de reatividade de Tsa1 e Tsa2 com hidroperóxidos orgânicos naturais tais como peróxido de ácido oleico, ácido linoleico e colesterol, dentre outros. Além disso, a análise da susceptibilidade a superoxidação por esses hidroperóxidos é de grande importância, pois pode contribuir para o entendimento em detalhes deste fenômeno *in vivo*.

5- Avaliação do papel da Phe45 e Leu41 na atividade de Tsa1

As análises estruturais de estruturas de diferentes Prx revelaram que a Thr44 possui interações polares com Phe45 e a Leu41. Essas interações aparentemente apresentam grande importância para a atividade das 2-Cys Prx, assim estudos utilizando mutagênese sítio dirigida apresentam-se fundamentais para determinar a real importância dessas interações e podem contribuir para o entendimento da formação do complexo de transição.

Abstract: Typical 2-Cys Peroxiredoxins (2-Cys Prxs) are proteins which use a reactive cysteine (Cys_P) to reduce hydroperoxides at extraordinary rates. Cys_P , together with a Thr (or Ser) and an Arg, compose the catalytic triad. During catalysis, 2-Cys Prx switch between decamer and dimers in a redox dependent manner. Analysis of yeast Tsa1 structure revealed a highly conserved non-conventional hydrogen bond ($\text{CH}-\pi$) between Thr44 of a dimer with Tyr77 of adjacent dimer. Investigation of Tsa1 proteins mutated at Thr44 indicated that Thr44-Tyr77 bond stabilizes decamer structure. As a general trend, mutations favoring the dimer structure also provoked decreased reactivity, suggesting that Thr44 links oligomeric state with peroxidase activity of Tsa1. Moreover, $\text{Tsa1}^{\text{Y77A}}$ mutant appeared as dimer and displayed reduced peroxidase activity, further indicating that Thr44-Tyr77 interaction is relevant for decamer stabilization. The results indicated that the conserved Thr residue displays roles in both decamerization and reactivity towards hydroperoxide of 2-Cys Prx.

Introduction

Typical 2-Cys peroxiredoxins (2-Cys Prx) from the Prx1/AhpC sub-group comprise a large class of thiol-specific antioxidant enzymes able to reduce hydroperoxides with high efficiency (10^6 - $10^8 \text{ M}^{-1} \text{ s}^{-1}$) and specificity¹⁻⁵. In the catalysis, the typical 2-Cys Prx use one conserved cysteine residue, called peroxidatic cysteine (Cys_P), which is responsible for the reduction of hydroperoxide, forming a sulfenic acid in the Cys_P (Cys_P-SOH). The basic units of these enzymes are homodimers (α_2) and during the catalytic cycle a second Cys residue, the so-called resolving cysteine (Cys_R) reacts with the Cys_P in sulfenic acid form of the adjacent monomer to form an intermolecular disulfide bond (reviewed in 6,7). A partial unfolding of the α helix containing Cys_P is required for the inter-molecular disulfide formation and thioredoxin (Trx) is commonly the electron donor to reduce the disulfide^{6,7}. Therefore, during catalysis, Prx1/AhpC enzymes assume two structural states: Fully Folded (FF) and locally unfolded (LU). Alternatively, Cys_P-SOH can further react with additional hydroperoxide molecules giving rise to overoxidized states such as sulfinic (Cys_P-SO₂H) and sulfonic (Cys_P-SO₃H⁻) acids (Figure 1). These overoxidized forms are not reducible by Trx. In eukaryotic organisms, Cys_P-SO₂H can be reduced back to Cys_P-SOH by a sulfiredoxin catalyzed reaction in a process dependent on ATP⁶.

In the FF state, Cys_P is located in the first turn of an α -helix, surrounded by the Thr (or Ser, in some cases) and the Arg^{7,8}. The three residues compose the so called Prx catalytic triad, which is implicated in the reactivity and specificity of Prx towards hydroperoxides^{6,7}. Transient interactions in the active site of Prxs are thought to play crucial roles, by stabilizing the transition state of a S_N2 reaction. In the transition state, the nucleophilicity of the thiolate and the electrophilicity of the hydroperoxide are both increased^{9,10}. Some studies revealed the importance of Arg residue to Prx reactivity, since the substitution of the residue profoundly

affects Cys_P reactivity¹¹⁻¹⁵. In contrast, studies involving the substitution of the conserved Thr residue are very scarce^{14,15}.

Another intriguing feature of Prx1/AhpC enzymes is their ability to switch among distinct quaternary structures, which is affected by redox state among other factors^{6,7,13-19}. Prx1/AhpC enzymes are α_2 homodimers that can associate in $(\alpha_2)_5$ decamers, *i.e.* pentamers of dimers. The factors governing the stabilities and possible significance of these distinct quaternary structures are not completely understood, but intermolecular disulfide formation favors dimer configuration. Noteworthy, in AhpC from *Salmonella typhimurium* (StAhpC), decamerization was associated with an increase in the peroxidase activity¹. Therefore, reduced or overoxidized Prx1/AhpC enzymes appear preferentially as decamers (or even higher molecular weight complexes), whereas intermolecular disulfide destabilize decamers into dimers^{1,18-21}.

Saccharomyces cerevisiae presents two very similar cytosolic 2-Cys Prx enzymes, named Thiol specific antioxidant (Tsa1 and Tsa2 - 96% of similarity and 86% of identity)^{22,23}. One of the few differences in the primary structure between these two enzymes is the fact that Tsa1 possesses a Thr residue in the catalytic triad (Thr44), whereas Tsa2 presents a serine residue (Ser⁴⁴). We had observed before that Tsa1 and Tsa2 reactivity towards hydrogen peroxide is very similar ($2.2 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ to Tsa1 and $1.3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ to Tsa2), but their Cys_P pK_a values differ significantly².

In this work, analysis of all the available 2-Cys Prx structures showed that the catalytic Thr (Thr44 in yeast Tsa1) is located at the interface between two dimers, making a non-conventional hydrogen bond with the π system of a Tyr/Phe residue (Tyr77 in yeast Tsa1) (CH- π bond) of the adjacent dimer. Replacements of Thr44 to distinct residues altered the quaternary structure and the activity of the enzyme. Together, our results indicate that Thr44

displays roles in the stabilization of Tsa1 decameric structure and also in hydroperoxide reduction.

Results

Structural characterization of Tsa1 mutants - Reversible transition between dimer and decamer is a remarkable feature of 2-Cys Prx with consequences in their activity^{1,6,7,13,19,21}. Tsa1 crystallographic structure²⁴ was re-analyzed (Figures 2A and 2B). In reduced form, the $(\alpha_2)_5$ decamer is stabilized by several non-covalent interactions at the dimer-dimer interface (Figure 2C). Among these interactions, the C γ atom of Thr44 acts as hydrogen-bond donor to the π -system of Tyr77 (Figure 2D). Such CH- π bond is a non-conventional hydrogen bond that plays important contributions in protein structure and function (reviewed in 25,26). In fact, all five dimer-dimer interfaces of the Tsa1 structure have two CH- π hydrogen bonds between Thr44 and Tyr77 residues (Figure 3A). The presence of CH- π hydrogen bonds is supported by the fact that the angles (113.23 - 134.40°) and distances (3.30 - 3.68 Å) measured are consistent with such kind of interaction^{25,26}. The described CH- π hydrogen bond involves residues that are part of the so-called region I (Thr44) and region II (Tyr77), which are complementary at the dimer-dimer interface¹⁹.

Remarkably, CH- π hydrogen bonds between the catalytic Thr and Tyr of the adjacent dimer are fully conserved among all available structures of 2-Cys Prx (Prx1/AhpC) in the FF state (Figures 3 A-C, 3E). In some cases, Tyr (Tyr77 in yeast Tsa1) is substituted by a Phe residue, which also has an aromatic side chain and therefore can accept H bonds through electrons of its π -system (Figures 3 A-C, 3E; See Supplementary Fig. 1). In the LU state, the orientation between Thr44 and Tyr77 residues changes, and consequently the CH- π hydrogen bond is disrupted (Figures 3D,F).

According to our analysis, the catalytic Thr participates not only in catalysis^{9,10}, but also displays a structural role. While Thr44 C γ atom is involved in the interaction with the

neighbor dimer, the O γ atom has a polar interaction with the S γ atom of CysP, which is also stabilized by polar contacts with the guanidine group of Arg123 (Figures 2D, 3B). Therefore, we hypothesized that substitution of Thr44 by other residues would affect decamer stability by disturbing the two CH- π hydrogen bonds per interface, which might also destabilize other neighbor non covalent bonds at the dimer-dimer interface that are important for decamer stabilization. Noteworthy, the catalytic triad of Tsa1 is located near the dimer-dimer interface delimited by Tyr77 (see Supplementary Fig. 2), with Thr44 providing physical interaction between the catalytic center and the dimer-dimer interface.

To experimentally evaluate the effects of Thr44 substitutions on the Tsa1 quaternary structure, we employed size exclusion chromatography (SEC). Samples were reduced with 5 mM tris(2-carboxyethyl)phosphine (TCEP) or previously reduced with TCEP (5 mM) and then oxidized with H₂O₂ (1.2 eq.). Under reducing conditions, Tsa1^{WT}, Tsa1^{T44A} and Tsa1^{T44S} eluted as decamers (Figures 4A-C, solid lines), whereas Tsa1^{T44V} eluted as a mixture of dimers and decamers, with dimeric forms being clearly predominant (Figure 4D, solid line). As expected, the oxidized (disulfide) samples favored dimerization⁷ as compared with the reduced forms (Figure 4, dashed lines). The exception was Tsa1^{T44S} that migrated exclusively as decamers in both oxidized and reduced forms (Figure 4C, dashed line). In contrast, Tsa1^{T44V} migrated mainly as dimer (Figure 4D, dashed line). With intermediate behavior, equivalent amounts of dimers and decamers of Tsa1^{WT} and Tsa1^{T44A} were detected in oxidizing conditions (Figures 4A,B, dashed lines). In summary, Thr mutations provoked dramatic effects on quaternary structure, with T44S substitution favoring decamerization and T44V favoring dimerization. In the case of the Arg123 mutations, changes in SEC profiles were not so drastic. Tsa1^{R123K} eluted predominantly as a decamer (Figure 4F) and Tsa1^{R123G} migrated mainly as dimer in oxidizing conditions (Figure 4E).

Finally, to check if the Thr44 or Arg123 amino acids substitutions provoked major perturbations on the overall Tsa1 structure, circular dichroism (CD) analysis were carried out. All CD spectra indicated that the amino acid substitutions did not provoke perturbations in the content of secondary structures (see Supplementary Fig. 3). The CD spectra for all enzymes were consistent with α helix content of about 33% and about 20% of β sheet, which is agreement with Tsa1 crystallographic data²⁴.

Kinetic characterization of Tsa1 mutants for Thr44 and Arg123 - Next, we examined the effects of the mutations on Tsa1 reactivity towards hydroperoxides using the Trx system (Thioredoxin 1, Thioredoxin reductase 1 [TrxR1] and NADPH) coupled assay. Tsa1^{WT} and Tsa1^{T44S} presented similar catalytic efficiencies towards hydrogen peroxide (Figures 5A,C; Table 1). Tsa1^{T44A} presented a slight decrease in activity (Figure 5B; Table 1). In contrast, Tsa1^{T44V} presented a very high K_M (519.9 μ M) and the catalytic efficiency for hydrogen peroxide decreased two orders of magnitude (Figure 5D; Table 1). In human PrxV, T44V mutation also decreased the second order rate constant of the reaction with hydrogen peroxide by a factor of one thousand¹⁵. All kinetic parameters were determined under conditions where thioredoxin (at 2 μ M) was not limiting the catalysis (see Supplementary Fig. 4).

In the case of cumene hydroperoxide (CHP) reduction, Tsa1^{WT} and Tsa1^{T44S} also presented similar kinetic parameters (Insets Figures 5A,C; Table 1). In contrast to hydrogen peroxide reduction, Tsa1^{T44A} presented very high K_M (334.3 μ M) for CHP and consequently a four-fold decrease in the catalytic efficiency (Inset Figure 5B; Table 1). In the case of Tsa1^{T44V} mutant, an even more drastic drop in the reduction of CHP was observed (Inset Figure 6D), precluding the determination of the kinetic parameters. Similar results were observed for *L. donovani* TXNPx¹⁴. Therefore, mutations eliminating the hydroxyl group from the side chain impair more CHP reduction than hydrogen peroxide reduction. The

factors underlying this phenomenon are not clear, and may be related with the distinct effects of amino acid side chains on stabilization of the respective transition states with hydrogen peroxide and CHP; and/or with the release of the corresponding leaving groups.

We also evaluated the effects of Thr mutations by non-reducing SDS-PAGE. Reduced proteins were oxidized with three equivalents of hydrogen peroxide or CHP and the disappearance of monomers were followed. Consistent with the thioredoxin-coupled assay, among the three mutants, only Tsa^{T44V} presented a significant delay in disulfide formation for both hydrogen peroxide and CHP (see Supplementary Fig. 5 and 6). To investigate the effects of Thr44 substitutions on Tsa1 reduction by 1,4 dithiotreitol (DTT) or by Trx1, pre-oxidized enzymes were treated with different amounts of DTT (1-100 eq) or Trx (1-25 eq) at short intervals. Reduction of wild type and mutant proteins proceeded similarly, indicating that the residues at position 44 had a minor role in the reduction step (see Supplementary Fig. 7 and 8).

In the case of Arg123 mutants, in agreement with previous reports^{11,12,14,15}, $\text{Tsa1}^{\text{R123G}}$ and $\text{Tsa1}^{\text{R123K}}$ displayed only residual thioredoxin peroxidase activities (Figure 6A). As an independent and confirmatory assay, we evaluated disulfide formation in $\text{Tsa1}^{\text{R123G}}$ and $\text{Tsa1}^{\text{R123K}}$ from pre-reduced samples treated with hydrogen peroxide in non-reducing SDS-PAGE. Disulfide bond was rapidly formed in Tsa1^{WT} (10 seconds or less; Figure 6B). In contrast, replacement of Arg123 resulted in a substantial delay of disulfide formation, since monomeric bands were still detected even after 10 min of reaction with H_2O_2 (Figures 6C, D). Thus, both substitutions of Arg123 resulted in great drop of Tsa1 reactivity towards hydroperoxides.

Determination of apparent second order rate constants of the reaction of Tsa1 proteins with hydroperoxides - The interpretation of the results obtained by the Trx coupled assay is not

always straightforward, among other reasons because the overall catalytic cycle of 2-Cys Prx enzymes is complex involving three reactions (hydroperoxide reduction; condensation; disulfide reduction) and conformational changes (LU-FF transitions; dimer-decamer switches)⁷. Therefore, direct rate constants between hydroperoxides and reduced Tsa1 proteins were determined taking advantage of the change in their intrinsic fluorescence upon oxidation (Figure 7A). Such an overall decay was shown to be proportional to substoichiometric concentrations of hydrogen peroxide but levelled-off with stoichiometric or higher hydroperoxide concentration (Figure 7B), indicating Cys_p oxidation. Under pseudo first-order conditions (excess of peroxide), a two phase kinetics was observed for wild type Tsa1 (Figure 8A). In the first phase, the drop in fluorescence was very rapid (first 5 ms), justifying the apparent lag time, which coincides with the mixing time of the instrument (approximately 2 ms). The second and slower phase resulted in a fluorescence increase, and its meaning remains unclear at this point.

Recently, a similar kinetic profile was described for a StAhpC²⁷. To be able to fit the experimental data, the authors proposed a typical Michaelis-Menten model. In the first step, hydrogen peroxide would reversibly bind into StAhpC catalytic site, forming a Michaelis-Menten type of complex, followed by Cys_p peroxidation (which was associated to the fast fluorescence decay) and resolution (which was associated to second fluorescence increase phase). In our case and our experimental conditions, however, the raising in fluorescence appears to be dependent on hydroperoxide concentration (Figures 7B,C), suggesting unfavorable peroxide and Prx equilibrium or that overoxidation might contribute to it, although neither hypothesis have been pursued so far. Nevertheless, the initial rapid fluorescence decay increases linearly with both Prx and peroxide concentrations and is accompanied by loss of Tsa1 peroxidase activity, indicating that this phase is associated with Cys_p oxidation. To test this assumption, we determined what would be the rate constant of

Cys_p oxidation under pseudo first-order conditions, fitting the fast decay in the fluorescence to a single first-order exponential equation for the wild type enzyme, since we have previously determined this rate constant by an independent competitive kinetic approach². In this way, the rate constant for the Tsa1^{WT} oxidation by hydrogen peroxide was $5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, which agrees well with the value previously determined by the competitive assay². In addition, the second order rate constant for the Tsa1^{WT} and Tsa1^{T44S} oxidation by hydrogen peroxide and by CHP were similar and in the $10^7 \text{ M}^{-1} \text{ s}^{-1}$ range (Table 2), again in agreement to previous determinations². These convergences stimulated us to apply the same approach for the remaining Tsa1 mutants. For Tsa1^{T44A} and Tsa1^{T44V}, a decrease in reactivity was observed for both enzymes, and once again the valine mutant was the less reactive (Table 2). Nevertheless, the Tsa1^{T44A} was still quite reactive: one thousand times fold faster than free Cys²⁸, while the corresponding rate constants for the oxidation of Tsa1^{T44V} could not be determined due to its very low reactivity.

Therefore, Tsa1 from *S. cerevisiae* and StAhpC display different properties related to the dependence on hydrogen peroxide in the second phase with fluorescence increase. This difference might be related with the positions of the respective Trp residues. Noteworthy, Trp residues close to the resolving Cys in the two 2-Cys Prx are strikingly different (Figures 7D-E). Another factor that might contribute to this different fluorimetric behavior is that Tsa1 is sensitive to overoxidation, whereas StAhpC is not²⁹.

Values for catalytic efficiencies (k_{cat}/K_M) obtained were consistently three orders of magnitude lower than direct rate constant measures by the intrinsic fluorescence. Probably, some other reaction or structural rearrangements is limiting the overall turnover under catalytic conditions (Figure 1). Nevertheless, the same trend was observed whatever the approach (Trx coupled or fluorimetric assay) employed. Mutation of Thr44 by Val decreased the ability of Tsa1 to reduce hydroperoxide by several orders of magnitude, whereas T44A

induced a less pronounced effect. These results indicate the importance of the polar hydroxyl group in the catalysis. Nevertheless, since mutants Tsa1^{R123G} and Tsa1^{R123K} displayed only residual activity, Arg123 appears to play the major role in Tsa1 reactivity.

Relationship between quaternary structures and catalytic activity of 2-Cys Prx – The results presented so far indicated that Thr44 plays roles on both decamer stabilization and peroxidase activity. To gain further insights on the roles of the non-conventional Thr44 - Tyr77 CH-π hydrogen bond, Tsa1^{Y77A} mutant was also produced. Furthermore, Tsa1^{S78D} mutant was generated based on the information that in StAhpC and in HsPrx4, similar substitution provoked dimer destabilization^{1,20}. Thr77 in StAhpC (Ser78 in Tsa1) is located in the decameric interface of the enzyme but does not have direct interactions with the active site residues, including CysP. Substitution of Thr77 by an aspartic acid in StAhpC precluded decamer formation¹. Yeast Tsa2 (86% of amino acid identity with Tsa1) was also analyzed, since this enzyme naturally presents a Ser in the position equivalent of Thr44 in Tsa1².

Similar to the Tsa1^{T44S} mutant, Tsa2 migrated exclusively as decamer independently of redox state of the enzyme (Figure 8A). In contrast, Tsa1^{Y77A} always eluted as dimer (Figure 8B). Once again these results indicated that the Thr44-Tyr77 bond favors dimer-dimer interaction and that Ser in place of Thr stabilize Tsa1/Tsa2 in the decameric state. The peroxidase activity of Tsa1^{Y77A} was highly affected, which is in agreement with the results obtained with Tsa1^{T44V} (Figure 5D). In contrast, Tsa2 efficiently reduced both CHP and hydrogen peroxide (Figures 5B; 8D,E; Table 2). As predicted, Tsa1^{S78D} also eluted as dimers, independently of the redox state (Figure 8F) and the peroxidase activity was only residual in the Trx coupled assay (Figure 8G). Actually, S78D mutation provoked a more drastic result than the corresponding experiment with StAhpC¹. As an independent and confirmatory assay, non-reducing SDS PAGE revealed that rates of disulfide formation in Tsa1^{Y77A} and Tsa1^{S78D}

were very slow (Figure 8H,I). Finally, the second order rate constants for Tsa2 oxidation by hydrogen peroxide and CHP were similar to the corresponding rate constants for Tsa1 (Table 2; see Supplementary Fig. 9). In contrast, the reactivities of Tsa1^{Y77A} and Tsa1^{S78D} were extremely low, precluding the determination of the rate constants values by available methods (Table 2).

Discussion

Among Prx enzymes, the 2-Cys Prx (AhpC-Prx1) sub-group displays the remarkable capability to switch between dimers and decamers, which is part of the catalytic cycle⁷. Dimers and decamers are apparently in a dynamic process, in which redox state, pH and protein concentration, among other factors, shift the equilibrium to the dimer or to the decamer^{16,19,30,31}. In the reduced state, 2-Cys Prx enzymes are preferentially in the FF state as decamers, in an optimal conformation for hydroperoxide reduction⁷. After oxidation to sulfenic acid, a locally unfolding process must take place to allow approximation of the two Cys residues. This locally unfolding process destabilizes the decamer, favoring dimers⁷. Therefore, a weakly associated decamer (in the LU state) has been proposed as an intermediate between the FF decamer and the LU dimer¹⁹ and other intermediate oligomeric structures have also been frequently observed^{13,17}. Here, we present evidences that the highly conserved Thr residues in the active site (Thr44 in Tsa1) play also a structural role in the stabilization of Tsa1 as a FF decamer.

Through a comparative structural analysis of 2-Cys Prx enzymes, it became clear that although most residues in the dimer-dimer interface retain similar conformation between FF and LU states, the conserved Thr residue (Thr44 in Tsa1) rotates approximately 45° upon oxidation (Figure 3, compare panels C, E with D and F). This rotation is conserved in all of the analyzed structures and is associated with the disruption of the CH-π bond in the LU state.

Since there are two CH- π bond per dimer-dimer interface, it is possible that the linkage contributes to a higher decamer stability of the FF state as compared with the LU state^{7,19}. It should be taken into account that under the high protein concentrations required for crystallization, 2-Cys Prx enzymes tend to be stabilized as decamers, even in LU form. Indeed, it has been proposed that the LU decamers (“metastable oligomerization intermediate”) are less stable than the FF decamers^{7,19}. Disruption of two CH- π bond per dimer-dimer probably contributes to the FF to LU transition.

Other mutations in the dimer-dimer interface (Thr77 residue of StAhpC and Thr¹¹⁸ in Prx4) were reported to provoke major changes in the stability of dimers and decamers^{1,20}. However, crystal structures of these proteins did not reveal major alterations in the dimer-dimer interface. In most of these structures, 2-Cys Prx enzymes are in the LU state with an intermolecular disulfide bond and the active site Thr (Thr⁴³ in StAhpC) is rotated approximately 45°, which we describe above as a common feature for these enzymes in the LU state. Our structural analysis of StAhpC and Prx4 mutants indicated that subtle modifications in the dimer-dimer interface can provoke major changes in the dimer-decamer transitions at lower protein concentrations.

Therefore, mutations of residues in the dimer-dimer interface are not expected to result in major structural modifications. Nevertheless, some hypothesis for the structural roles of residues equivalent to Thr44 in Tsa1 can be raised based on our structural analysis and experimental data. Comparing wild type and mutant proteins, considering the amino acid at position 44 with similar polarity, we observed that residues with smaller side chains tend to stabilize the decamer. Indeed, Tsa1^{T44S} was only observed in the decameric form, whereas Tsa1^{WT} is found in both dimeric and decameric states. Tsa1^{T44A} was found in both dimeric and decameric states, whereas Tsa1^{T44V} was found mostly as dimer under both reducing and oxidizing conditions (Figure 4). These observations suggested a steric factor underlying the

decamer stability. In fact, the microenvironment around the active site Thr is crowded (Figure 9A-B) and re-accommodation of neighbor residues is likely to be required to allow a 45° rotation. Possibly, smaller side chains might allow softer FF–LU transitions, without major perturbations at the dimer-dimer interface. The extra C_γ in the Thr side chain (in comparison with Ser side chain) may create steric shock with neighbor residues, disfavoring the decameric state during the transition from FF to LU. Indeed, it is clear that the microenvironment around the active site Ser in AhpC from *A. xyloanus* (Figure 9C) is less crowded than Thr residues in similar LU structures. Proof of this concept will depend on the availability of the structure of a 2-Cys Prx in FF state with a Ser in the active site.

Apparently, not only the size, but also the hydroxyl group in the side chain stabilizes the decamer. Indeed, Tsa1^{WT} (with a Thr in position 44) is found in both dimeric and decameric states, whereas Tsa1^{T44V} was found mostly as dimer. Tsa1^{T44S} was only observed in the decameric form, whereas Tsa1^{T44A} was found in both dimeric and decameric states. The O atom in the side chain of Thr residues may perform distinct polar interactions in the FF and LU states possibly helping to stabilize 2-Cys Prx in the decameric form (Figure 9D-K). The few available structures of 2-Cys Prx in the dimeric form show the active site Thr of Prx1^{C83S} from *R. novergicus* participating in distinct polar interactions¹⁸ than in the FF and LU decamers.

Remarkably, Ser is a residue that has the two properties that appear to be important to stabilize the decamer, the small size and the hydroxyl group. Accordingly, Tsa2 is one 2-Cys Prx that naturally have a Ser residue occupying position 44 and was also found mainly in the decameric state (Figure 8).

The results described here are in line with previous studies showing that decamers display higher peroxidase activity than dimers¹. However, the implications of Thr44 mutations in Tsa1 are complex because the residue is also a member of the catalytic triad⁸. The hydroxyl

group of the conserved Thr plays a role in the catalytic properties of the enzyme by polar interaction with the hydroperoxide substrate^{9,10}. Nevertheless, Tsal^{T44A} remained quite reactive towards hydroperoxides ($10^4 \text{ M}^{-1}\text{s}^{-1}$) (Figure 7B; Table 2; see Supplementary Fig. 8A) as compared with ordinary thiols, such as free Cys or GSH.

2-Cys Prx enzymes display complex structural and biochemical properties, involving distinct quaternary structures and oxidation states, including overoxidized states. Our contribution here is to show that the active site Thr is involved in the stabilization of 2-Cys Prx decamers through the CH- π hydrogen bonds with Tyr/Phe residues of adjacent dimers in addition to be a member of the catalytic triad.

Acknowledgments

We acknowledge the financial support from the Fundação de Amparo à Pesquisa do Estado de São Paulo grants 07/50930-3 and 13/07937-8 (Redox Process in Biology and Medicine - REDOXOMA).

Author Contributions

C.A.T.Jr and M.C.S. performed point mutations expressed and purified the proteins. C.A.T.Jr, M.C.S., C.A.B., and M.H.T. performed steady state kinetic analysis and SEC and CD.; Spectrofluorometric approaches were performed C.A.T.Jr, R.R.G., J.C.T.Jr, C.J.N., S.P.L., and G.F.S.; C.A.T.Jr and M.A.O. executed the structural analysis. L.E.S.N., O.A. and M.A.O provided overall project supervision and wrote the paper along with C.A.T.Jr and M.C.S.

Figure 1

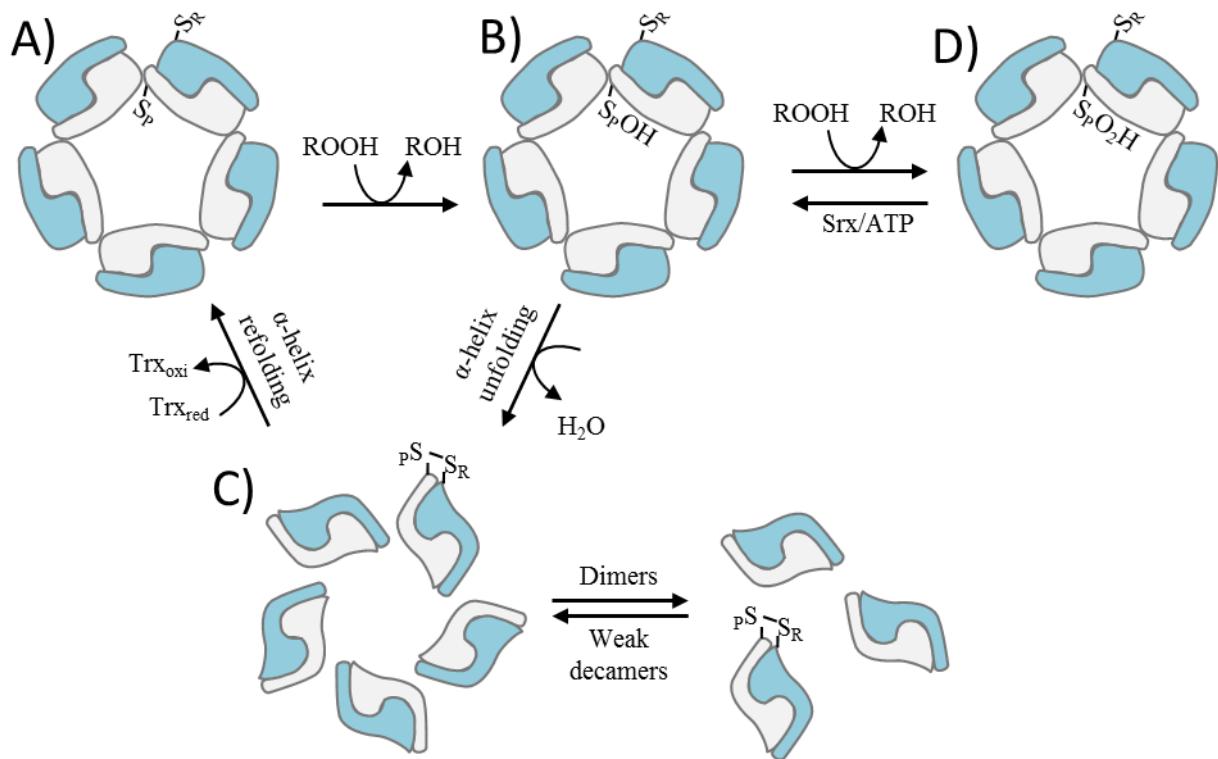

Figure 1. Proposed mechanism for 2-Cys Prx (AhpC-Prx1) reduction of hydroperoxides.

(a) Cys_P in the fully folded (FF) form (S_p^-) displays high reactivity towards hydroperoxides and favor the maintenance of the decamer in typical 2-Cys Prx. (b) The oxidation product (sulfenic acid - S_pOH) can have two outcomes: condensation or overoxidation. (c) Since the two Cys residues are far away in the FF form, a local unfolding should take place for the intermolecular disulfide bond formation, which induces the impairment of the decamer, being possible the appearance of dimers. The reduced form of typical 2-Cys Prx is regenerated by Trx, restarting the catalytical cycle. Additionally, sulfenic state of 2-Cys Prx (b) can be overoxidized (d) by reaction with a second molecule of hydroperoxide, inactivating the enzyme. This process can be reversed by Srx, with consumption of ATP.

Figure 2

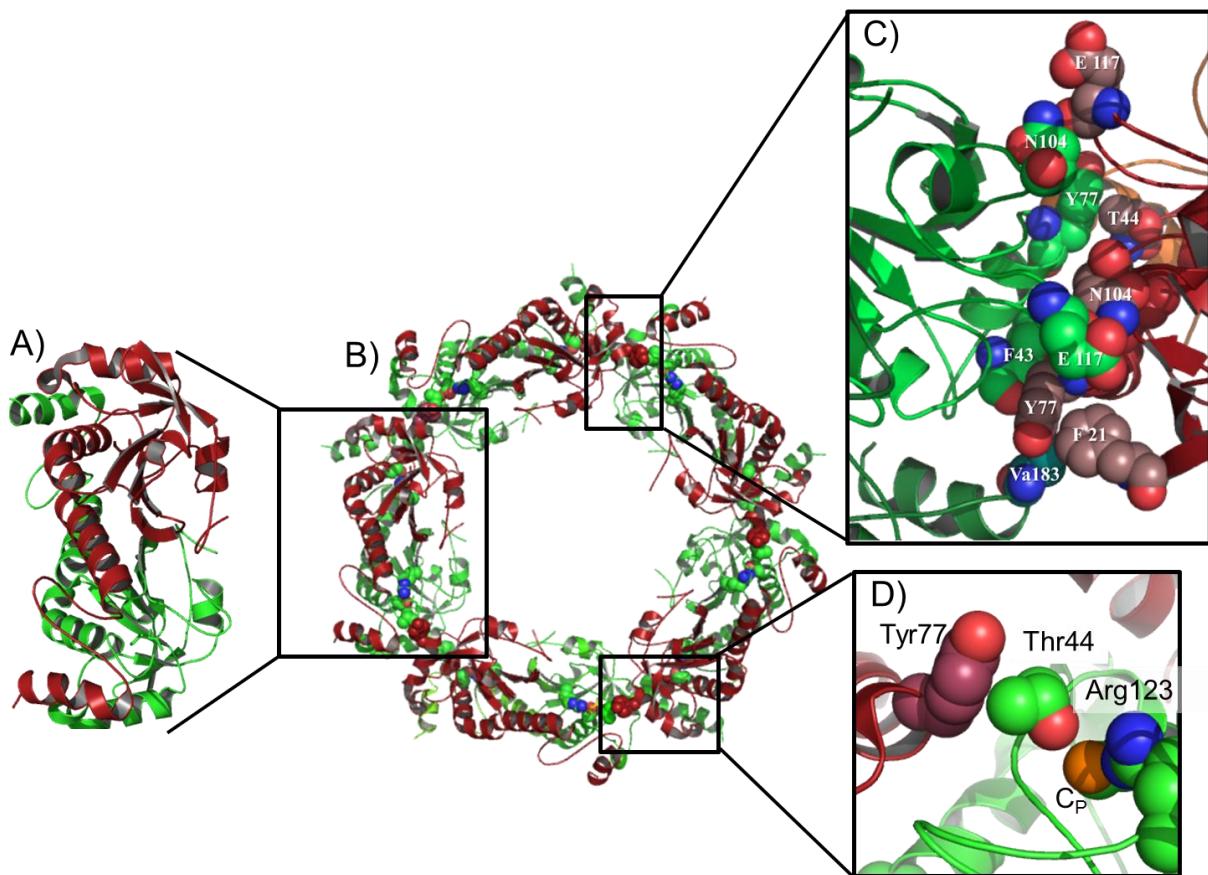

Figure 2. Decameric $\text{Tsa1}^{\text{C47S}}$ structure and decamer stabilization. (a) Tsa1 homodimer represented in cartoon with a monomer colored in green and the other in red. (b) Tsa1 decamer as a pentamer of homodimers. (c) Molecular interactions at the dimer-dimer interface in the $\text{Tsa1}^{\text{C47S}}$ crystallographic structure. Amino acid residues involved in the interactions between dimers are represented with spheres. (d) Thr44 CH- π bond with the Tyr77 of the adjacent dimer. The opposite extremity of Thr44 is involved with polar interactions with Cys_P S γ , which in turn is stabilized by guanidine group of the Arg123. For (c) and (d), the carbon atoms are represented by colors similar to the polypeptide chain to which they belong, whereas N = blue, O = red and S = orange.

Figure 3

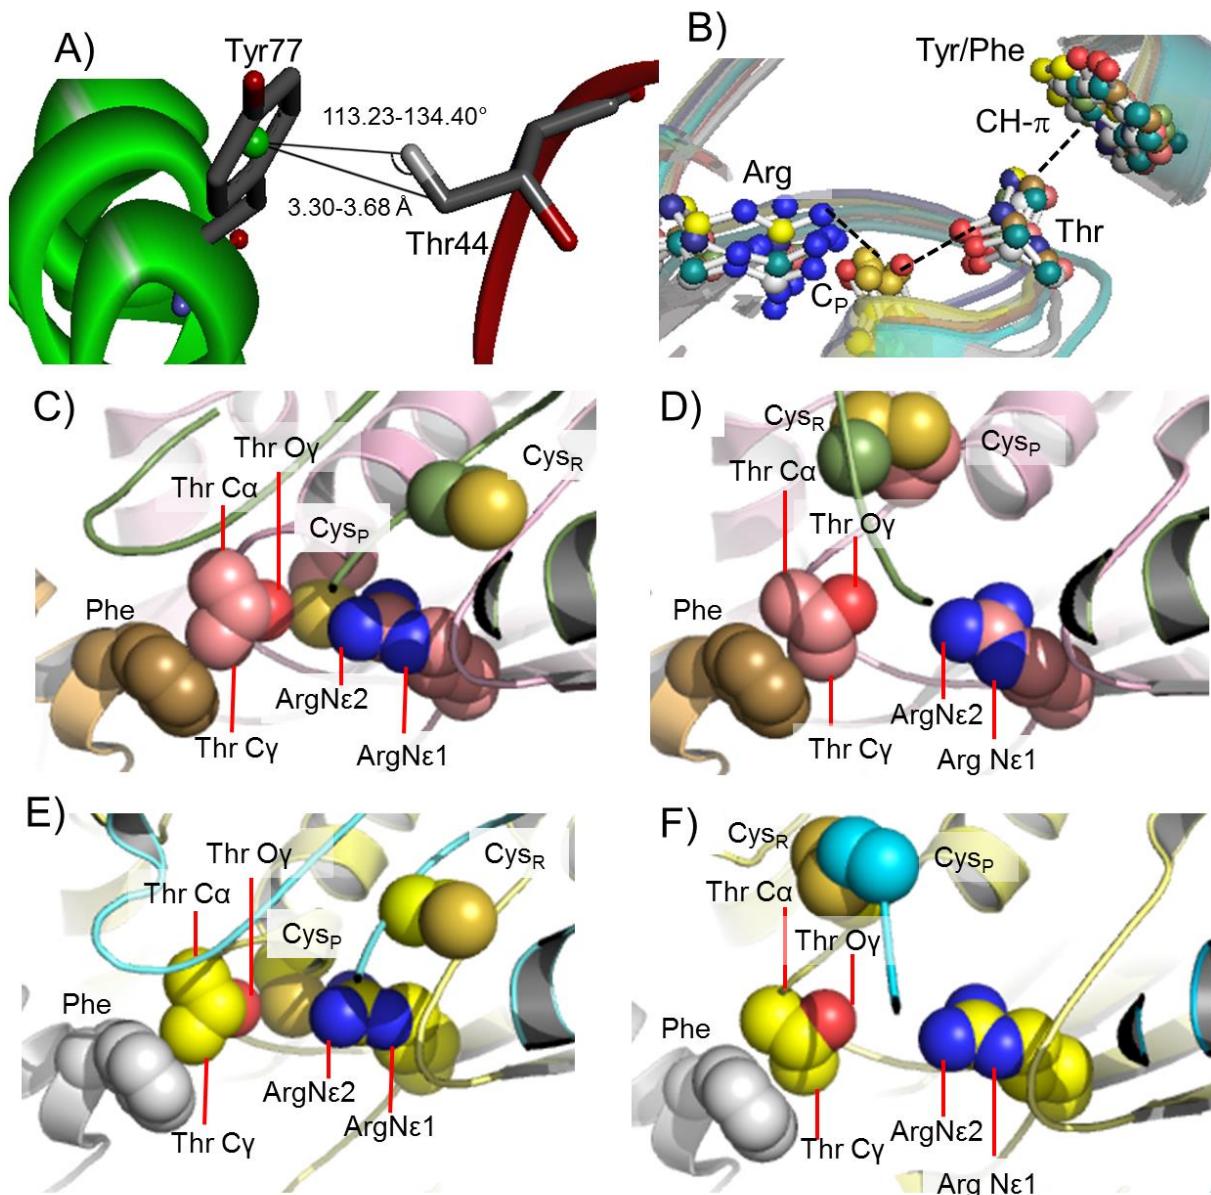

Figure 3. Interactions between Thr and Tyr (Phe) in reduced (FF state) or disulfide (LU state) forms of typical 2-Cys Prxs. (a) Diagram of Thr44 and Tyr77 from Tsa1 at the dimer-dimer interface, depicting the corresponding CH- π hydrogen bond. The graphic representation and the distances/angles were accessed using the program Discovery Studio 4.0 (Accelrys Software Inc., Discovery Studio Modeling Environment). (b) Overlap of the catalytic triad residues (Cys_P = C_p, Arg and Thr) and CH- π hydrogen bonds between Thr and Phe/Tyr residues of several 2-Cys Prx crystallographic structures. The enzymes are on FF state and depicted by different colors as follow: *Salmonella typhimurium* AhpC (yellow; 4MA9), *Leishmania major* PrxII (brown; 4K1F), *Schistosoma mansoni* Prx (white; 3ZTL),

Pseudosciaena crocea Prx4 (cyan; 3QPM), *Homo sapiens* sulfinilate form of Prx2 (red; 1QMV), *Rattus norvegicus* Prx1^{C51S} (dark green; 2Z9S) and *S. cerevisiae* Tsa1^{C47S} (dark blue; 2Z9S). The crystallographic structures of 2-Cys Prx in FF state of the wild type enzymes from *S. typhimurium* (**c**; 4MA9) and human Prx4 (**e**; 3TKP) shows and intimate hydrogen bond network between Phe-Thr-CysP-Arg which is lost with the disulfide formation of the LU state in *S. typhimurium* (**d**; 1YEP) and human Prx4 (**f**; 3TJB). The structures are represented in cartoon (pink and gold = AhpC; yellow and gray = Prx4) and the residues of catalytic triad and the conserved Tyr/Phe are represented by spheres. Carbon atoms are in same color of the cartoon representations. The other atoms follow the pattern: N = blue, O = red, S = orange.

Figure 4

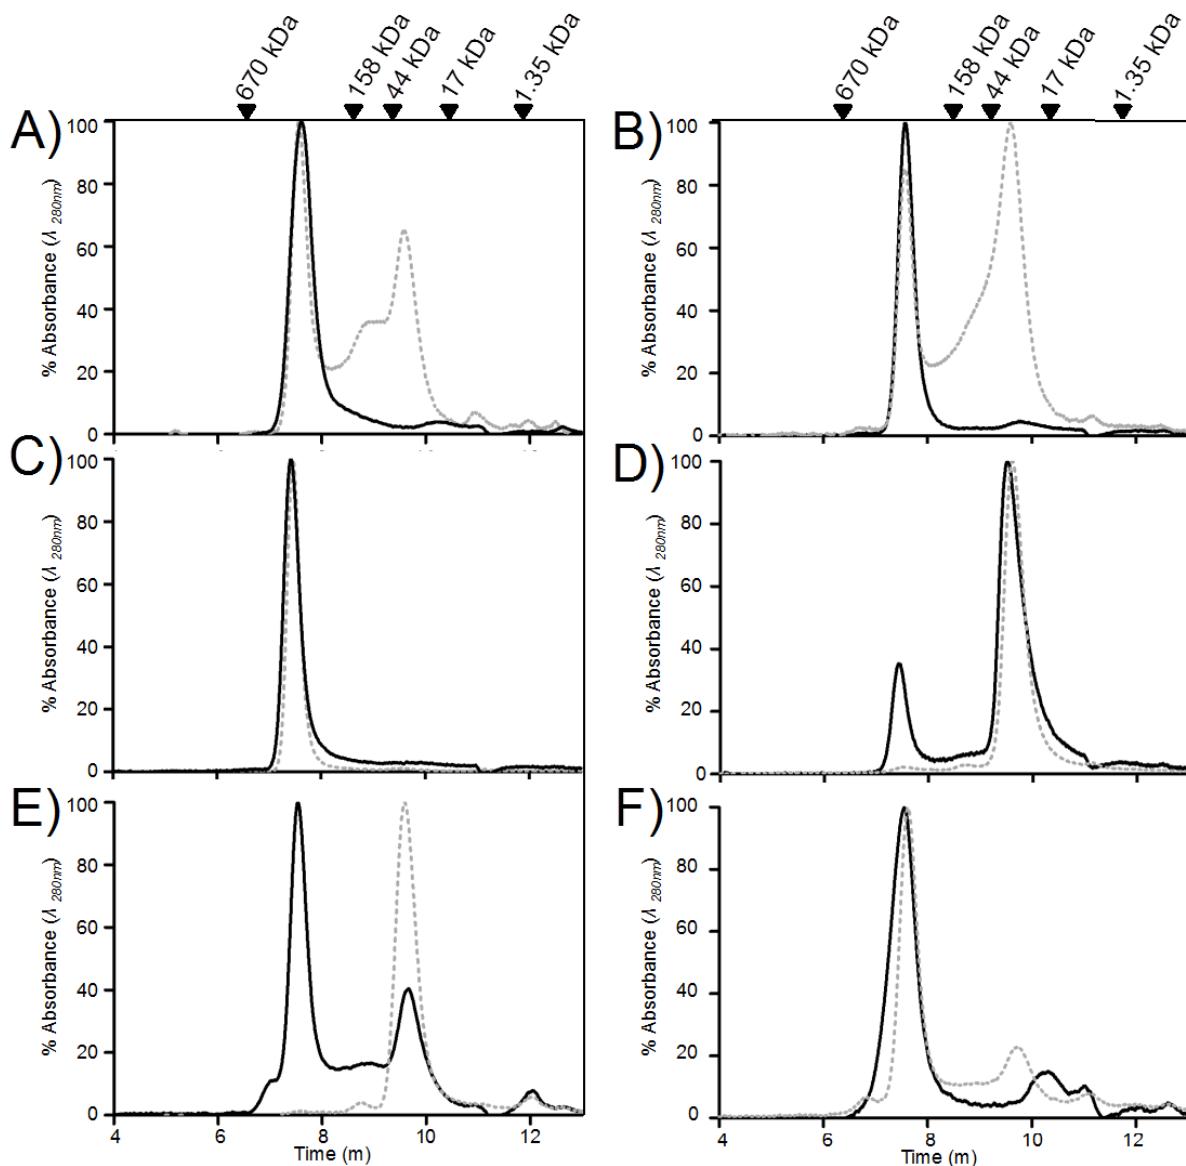

Figure 4. Size exclusion chromatography (SEC) profiles of Tsa1^{WT} and mutants in reduced and oxidized states. Samples were reduced with TCEP (5 mM; solid lines) or previously reduced with TCEP (5 mM) and then oxidized with hydrogen peroxide (1.2 molar equivalents; dashed lines) by 30 min at 25°C. Tsa1^{WT} (a), Tsa1^{T44A} (b), Tsa1^{T44S} (c), Tsa1^{T44V} (d), Tsa1^{R123G} (e) and Tsa1^{R123K} (f) at 50 μ M were injected into HPLC system equipped with Phenomenex BioSep-SEC-S3000 column with a flow rate of 1 mL/min. The molecular standards used were: bovine thyroglobulin (670 kDa), bovine gamma globulin (158 kDa), ovalbumin (44 kDa), myoglobin (17 kDa), vitamin B₁₂ (1.35 kDa) and are assigned on the top of the figure.

Figure 5

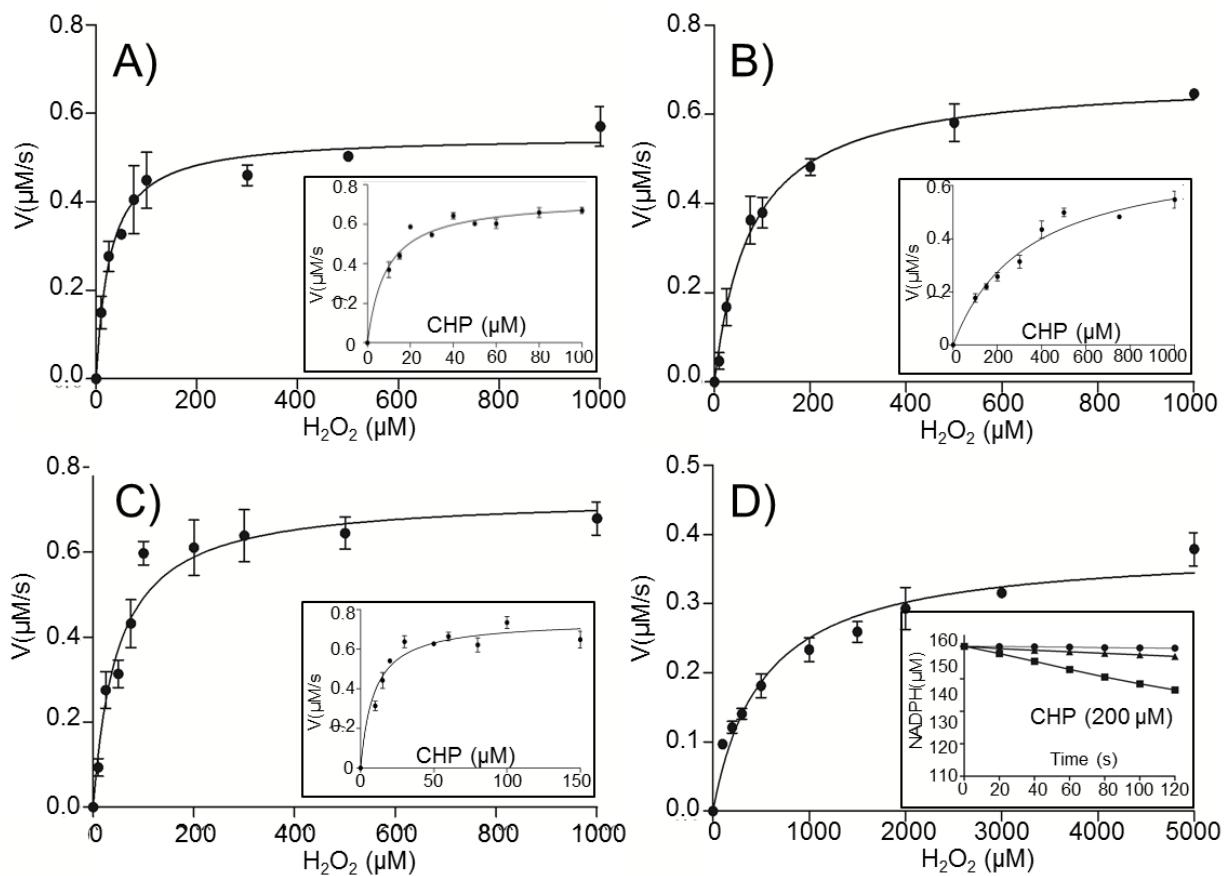

Figure 5. Steady state kinetics analysis of reduction by the Trx system of Tsa1 and mutants with increasing concentrations of hydrogen peroxide or cumene hydroperoxide (CHP). Tsa1^{WT} (a), Tsa1^{T44A} (b), Tsa1^{T44S} (c) and Tsa1^{T44V} (d) were incubated with Trx system (Prx = 1 μM ; Trx1 = 2 μM ; TrxR1 = 0.3 μM ; NADPH = 150 μM) in 50 mM HEPES (pH 7.4), 100 μM DTPA and 1 mM sodium azide at temperature of 30°C and variable concentrations of hydroperoxides as indicated in the x axis. The reactions were monitored by the consumption of NADPH spectrophotometrically at 340 nm. In the inset graphics, reactions using CHP instead of H_2O_2 are represented under the same experimental conditions, except for (d), since no NADPH consumption was observed. In this case, as an example, it is presented the reaction of 200 μM CHP with Tsa1^{T44V} (●), Tsa1^{WT} (■) as a positive control and in the absence of enzyme as a negative control (▲). The initial rate values to each reaction were adjusted in a Michaelis-Menten curve to obtain the kinetic parameters.

Figure 6

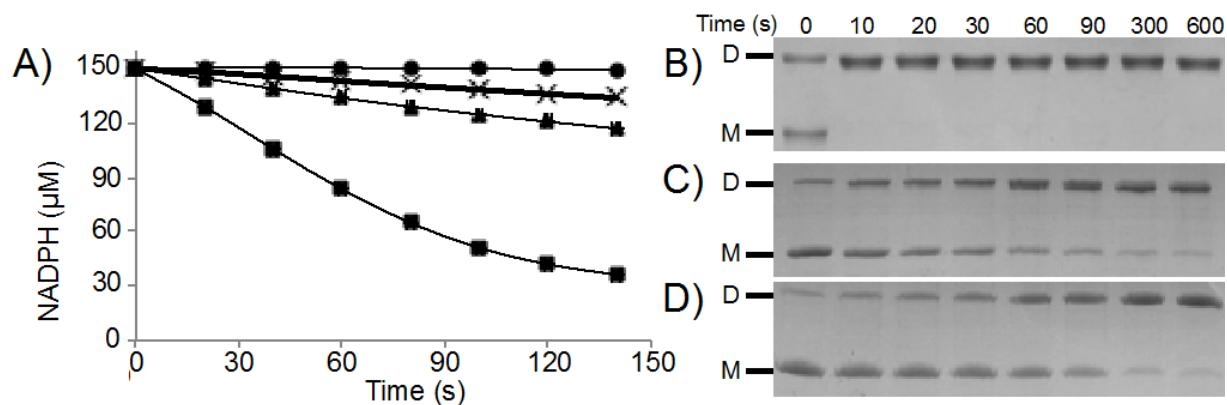

Figure 6. Kinetic characterization of Tsa1 mutants for Arg123. (a) Trx coupled peroxidase assay. Reactions were followed by the oxidation of NADPH ($\text{Abs}_{340 \text{ nm}}$) at 30°C in a 100 μl volume containing 150 μM NADPH; 200 μM hydrogen peroxide; 2 μM of *S. cerevisiae* Trx1; 0.3 μM of *S. cerevisiae* TrxR1 and 1 μM Tsa1^{WT} (■), Tsa1^{R123G} (×) or Tsa1^{R123K} (▲). Reactions without Tsa1 addition were also monitored as control (●). (b) to (d) non reducing SDS-PAGE assay for disulfide formation. Enzymes (b = Tsa1^{WT}; c = Tsa1^{R123G}; d = Tsa1^{R123K}) were pre-reduced with 20 mM DTT the excess was removed by gel filtration. Tsa1 and mutants (10 μM) were treated with three equivalents of H₂O₂. The experiments were performed in 10 mM HEPES (pH 7.4), 100 μM DTPA, 1 mM sodium azide at 25 °C. To stop the reaction, buffer containing NEM (50 mM), 4% SDS, 10% glycerol, 62.5 mM Tris-HCl (pH 6.8) was added at the times indicated at the top of the figure (10-600 s). D = dimer; M = monomer.

Figure 7

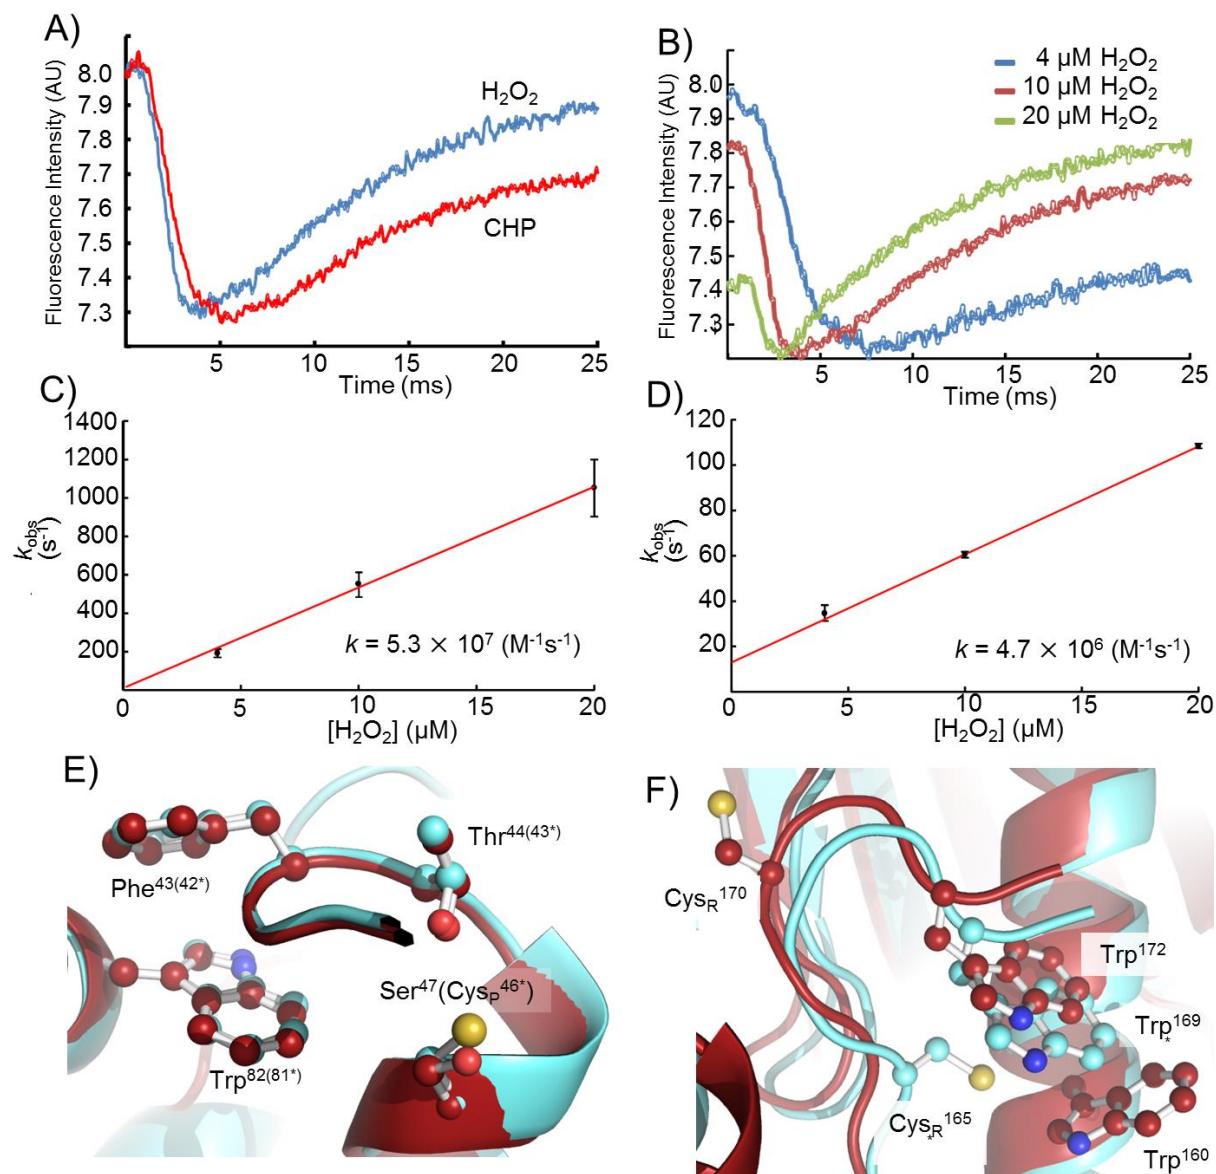

Figure 7. Hydroperoxide reduction by Tsa1 followed by changes in its intrinsic fluorescence. (a) Representative time course of Tsa1^{WT} ($1 \mu\text{M}$) oxidation by H_2O_2 or CHP ($20 \mu\text{M}$). (b) Oxidation of Tsa1^{WT} ($1 \mu\text{M}$) by increasing levels of H_2O_2 ($4, 10$ or $20 \mu\text{M}$). Enzymes were previously reduced with 20 mM DTT for 30 minutes at room temperature, and the excess was removed by gel filtration. Total intrinsic fluorescence decay upon oxidation by hydroperoxides were followed ($\lambda_{\text{ex}} = 280 \text{ nm}$) at 25°C . The assays were performed in 40 mM phosphate buffer (pH 7,4). The plots of the k_{obs} obtained to the first (c) and second (d) phases demonstrates the dependence on hydroperoxide concentration. The k_{obs} values were obtained by fitting the stopped-flow data to single exponential; second order rate constant was calculated from the slope of k_{obs} plot versus oxidant concentration. Structural comparison of

Trp residues between Tsa1 (3SBC, red) and StAhpC (4MA9, light blue) in the vicinity of Ser47 (substituting Cys_P) (**e**) and Cys_R (**f**). Striking differences are found in the position of Tsa1 Trp¹⁷² and Cys_R¹⁷⁰, and Trp¹⁶⁹ and Cys_R¹⁶⁵ of StAhpC. Furthermore, an additional Trp residue in Tsa1 is found close to Cys_R. The residues numbering refer to Tsa1 residues and those between parentheses and containing an asterisk are relative to StAhpC residues. The structures are represented in cartoon, while Trp and Cys residues are represented by balls and sticks. C = same color of the cartoon representations, N = blue, O = red, S = orange.

Figure 8

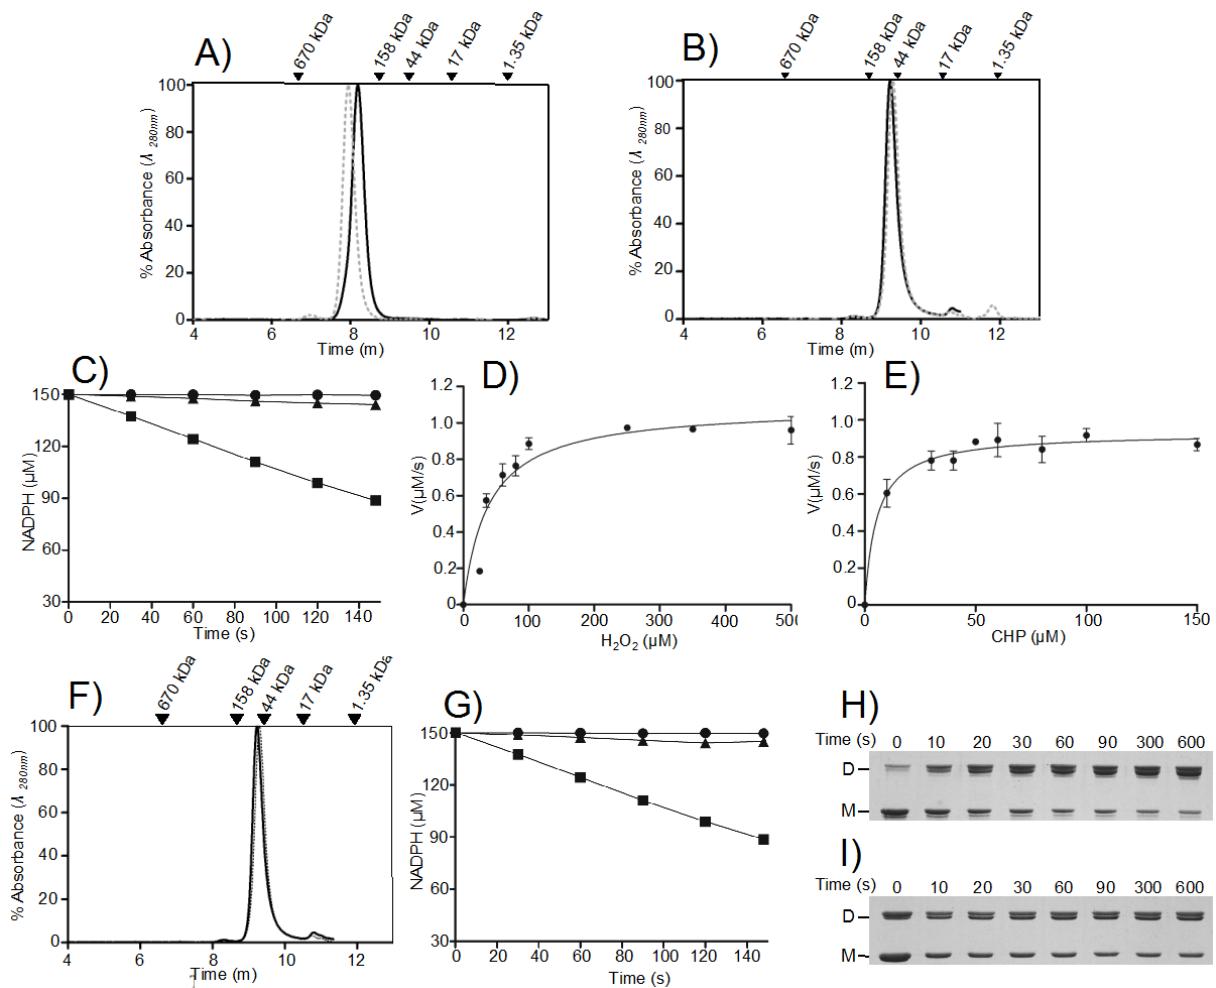

Figure 8. Structural and kinetic characterization of Tsa2, Tsa1^{Y77A} and Tsa1^{S78D}. Elution profiles of reduced (solid) and oxidized (dashed) Tsa2 (**a**) and Tsa1^{Y77A} (**b**) at 50 μM concentration in SEC, as described in Figure 4. (**c**) Trx coupled assay for H₂O₂ reduction; Tsa1^{WT} (■) or Tsa1^{Y77A} (▲) (1.0 μM). As control, reactions without Tsa1 were also monitored (●). Reactions were initiated by the addition of 200 μM H₂O₂. Trx coupled assay for Tsa2 using H₂O₂ (**d**) or CHP (**e**). In (**c**), (**d**) and (**e**), the experimental conditions and Michaelis-Menten plot were performed the same as presented in Figure 5. (**f**) SEC profiles of Tsa1^{S78D} in reduced (solid) and oxidized (dashed) states, under the same conditions as (**a**). (**g**) Trx coupled assay using Tsa1^{S78D}. Reactions containing Tsa1^{WT} (■), Tsa1^{S78D} (▲) or no Tsa1 (●) were performed as previously described for Tsa1^{Y77A}. Non reducing SDS-PAGE assay for disulfide formation after H₂O₂ treatment of the Tsa1^{Y77A} (**h**) and Tsa1^{S78D} (**i**). The pre-reduced and desalting enzymes (10 μM) were treated with three equivalents of H₂O₂. The experiments were performed at 25 °C in 10 mM HEPES (pH 7.4), 100 μM DTPA, 1 mM sodium azide. Reactions were stopped by addition of buffer containing 50 mM NEM, 4% SDS, 10%

glycerol, 62.5 mM Tris-HCl (pH 6.8) at the times indicated at the top of the figure (10-600 s).

D = dimer; M = monomer.

Figure 9.

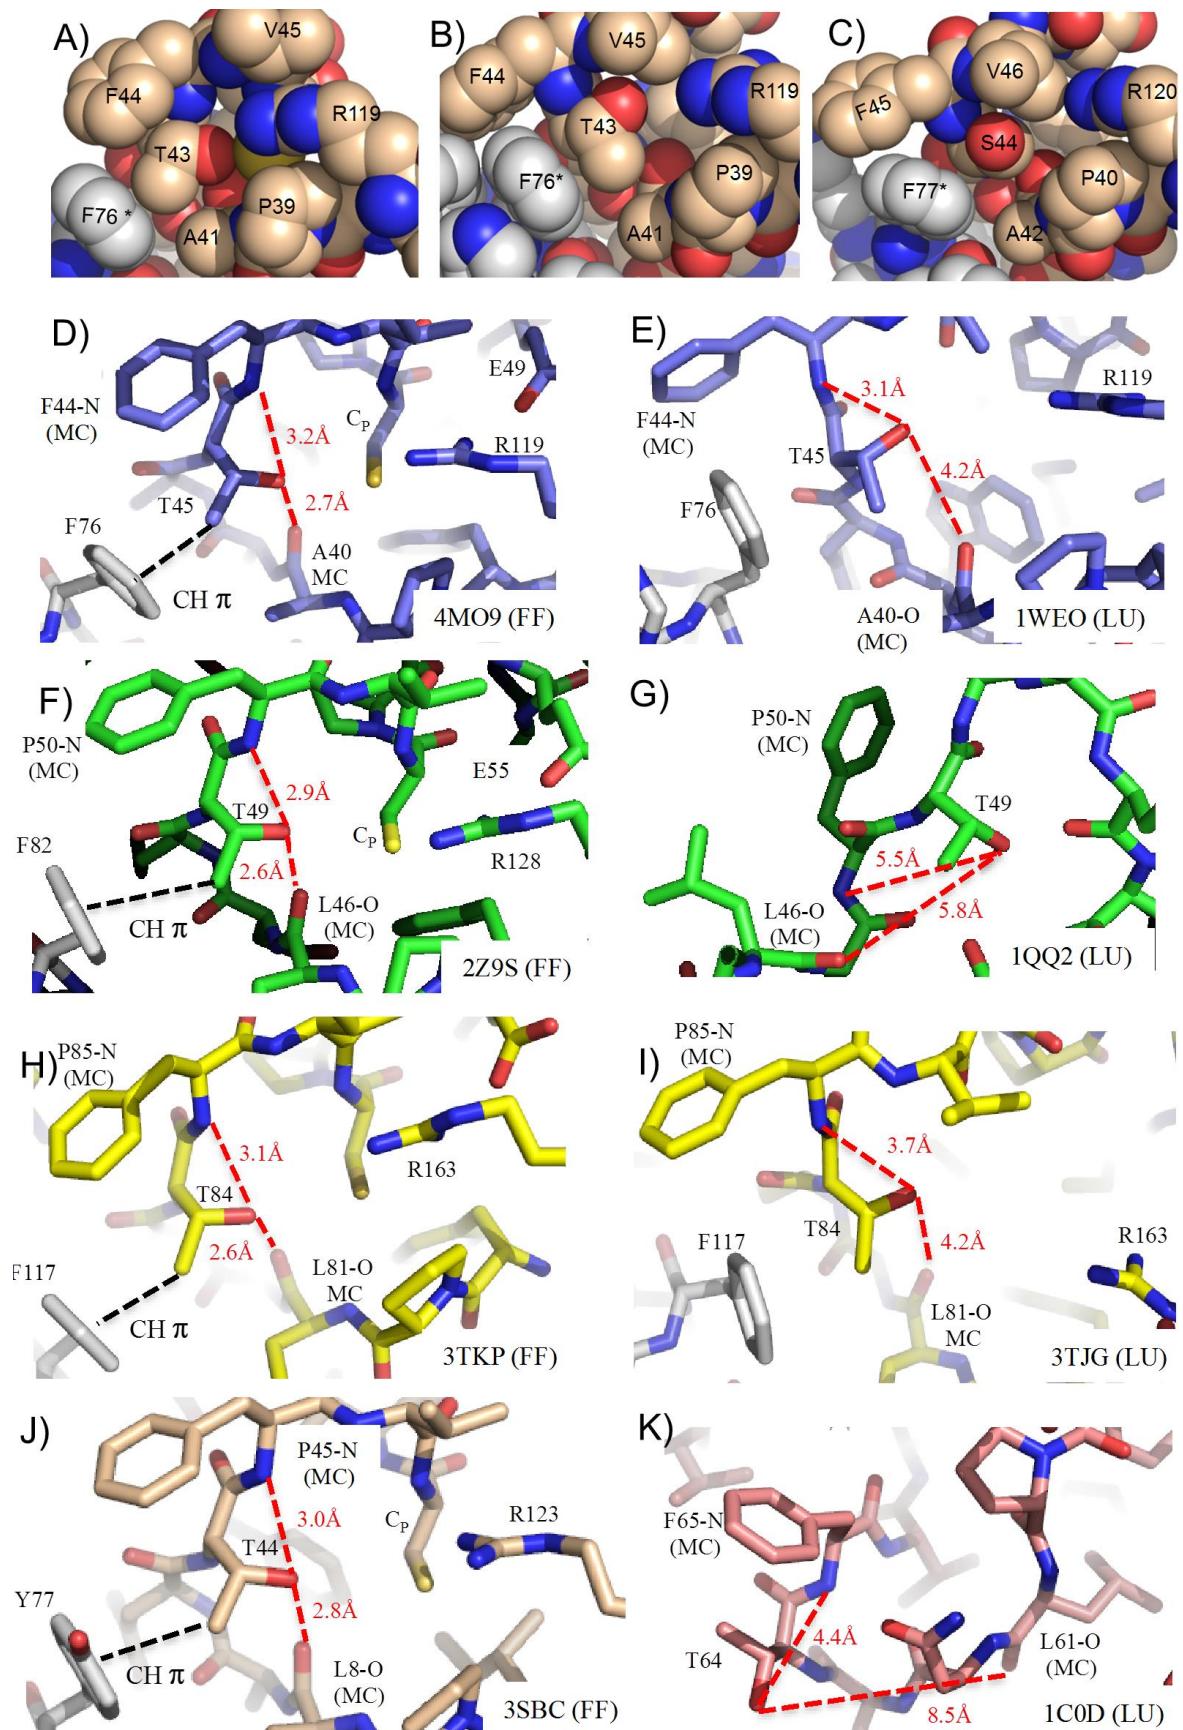

Figure 9. Environment around active site Thr/Ser residue in oxidized and reduced states of the 2-Cys Prxs. StAhpC active site pocket environment represented in spheres in reduced (**a**; 4MA9) and oxidized states (**b**; 1YEP). Structure of *A. xyloanus* 2-Cys Prx (presents natural replacement of active site Thr by Ser) in oxidized state (**c**; 1WE0). Atoms are colored as follow: C = beige, N = blue, O = red, S = orange. Polar interactions of the Thr O γ with the main chain amino (Phe) or carbonyl group (Ala/Leu) of *S. typhimurum* 2-Cys Prx (**d**, **e**), *R. novoguicus* Prx1 (**f**, **g**), human Prx4 (**h**, **i**) and *S. cerevisiae* Tsa1 (**j**) in FF (reduced; **d**, **f**, **h**, **j**) or LU (oxidized; **e**, **g**, **i**) state. As a consequence of FF-LU transition, the distances of polar interactions increase significantly. The higher distances among the enzymes analyzed in LU are from *R. novoguicus* Prx1 (**g**) and mitochondrial *Plasmodium falciparum* 2-Cys Prx (mPfPrx) (**k**). The carbon atoms to each monomer are represented by different colors: AhpC = purple and white; Prx1 = green and white; Prx4 = yellow and white; Tsa1 = beige and white; mPfPrx = rose and white. The remaining atoms are colored as follow: N = blue, O = red, S = orange. Red dashed line denotes the distance among the atoms in angstroms to perform polar interactions. The black dashed line denotes CH- π bond. MC denotes main chain. PDB code and oxidation state is discriminate at the right bottom of the figure.

Tables

Table 1. Apparent Michaelis-Menten parameters for Tsa1^{WT} and mutants. Mono-substrate approach was employed varying hydroperoxide concentrations. Rates were followed by NADPH oxidation. Tsa1^{WT} or mutants (1.0 μ M), Trx1 (2 μ M), TrxR1 (0.3 μ M), NADPH (150 μ M) and H₂O₂ or CHP. The experiments were performed at 30 °C. The results represent three independent experiments for each enzyme.

Online Methods

Site directed mutagenesis - The pET15b/*Tsa1* plasmid was used as template to generate the individual *Tsa1* mutants carrying Thr44 substitutions to Ala (*Tsa1*^{T44A}), Ser (*Tsa1*^{T44S}) and Val (*Tsa1*^{T44V}); Arg123 to Gly (*Tsa1*^{R123G}) and Lys (*Tsa1*^{R123K}); Tyr77 to Ala (*Tsa1*^{Y77A}) and Ser78 to Asp (*Tsa1*^{S78D}). The mutagenesis protocols were performed according manufacturer instructions, using Quick Change II Kit (Stratagene) and the following primers: *Tsa1*^{T44A}_F (5' TGGCCTTCGCTTCGTCTGT 3'), *Tsa1*^{T44A}_R (5' ACAGACGAAAGCGAAGGCCA 3'); *Tsa1*^{T44S}_F (5' TTGGCCTTCAGTTCGTCTGT 3'), *Tsa1*^{T44S}_R (5' ACAGACGAAACTGAAGGCCAA 3'); *Tsa1*^{T44V}_F (5' TTGGCCTTCGTTTCGTCTG 3'), *Tsa1*^{T44V}_R (5' CAGACGAAAACGAAGGCCAA 3'); *Tsa1*^{R123K}_F (5' GTCGCCTTGAAAGGTTGTT 3'), *Tsa1*^{R123K}_R (5' GAACAAACCTTCAAGGCGAC 3'); *Tsa1*^{R123G}_F (5' GTCGCCTTGGGAGGTTGTT 3'), *Tsa1*^{R123G}_R (5' GAACAAACCTCCAAGGCGAC 3'); *Tsa1*^{S78D}_F (5' TCCGAATACGACCTTTGGCA 3'), *Tsa1*^{S78D}_R (5' TGCCAAAAGGTCGTATTGGGA 3'), *Tsa1*^{Y77A}_F (5' GACTCCGAAGCCTCCCTTG 3'), *Tsa1*^{Y77A}_R (5' CAAAAGGGAGGCTTCGGAGTC 3'). The reaction products were treated with *Dpn*I to remove methylated original plasmids and *E. coli* XL1-Blue strain was used as host in the transformations. Single colonies were selected and their plasmids extracted and sequenced with BigDye Terminator v3.1 Cycle Sequencing Kit using the automatic sequencer ABI 3730 DNA Analyser (Thermo Scientific) to confirm codons substitutions. The plasmids carrying the point mutations were transformed in *E. coli* BL21 (*DE3*) strain by electroporation.

Protein expression and purification - Single colonies of *E. coli* BL21 (*DE3*) strain containing the pET15b/*tsa1*, pET15b/*tsa1*^{T44A}, pET15b/*tsa1*^{T44S}, pET15b/*tsa1*^{T44V} pET15b/*tsa1*^{R123G}, pET15b/*tsa1*^{R123K}, pET15b/*tsa1*^{Y77A}, pET15b/*tsa1*^{S78D} or pPROEx/*tsa2* plasmids were

inoculated in LB medium (20 ml) containing 0.1 mg ampicillin/mL overnight at 37 °C/250 rpm, transferred to 1 L of fresh LB medium, and cultured further until OD₆₀₀ reached 0.6–0.8. Then the expression of all proteins was induced by the addition of 0.3 mM isopropyl-1-thio-β-D-galactopyranoside (IPTG) at 37°C/3hs/250 rpm in an orbital shaker. Cells were harvested by centrifugation and cell pellets were resuspended in start buffer (50 mM sodium phosphate buffer, pH 7.4, 500 mM NaCl, 20 mM imidazole and 2 mM phenylmethyl sulfonyl fluoride - PMSF) and disrupted by sonication. The cell extracts were kept in ice during streptomycin sulfate (1%) treatment for 20 min. The supernatants were clarified by centrifugation, homogenized by filtration and purified by immobilized metal affinity chromatography (IMAC) using HisTrap column (GE Healthcare). Imidazole was removed by gel filtration using PD10 desalting column (GE Healthcare) and the purity of recombinant proteins was verified by SDS-PAGE.

Protein quantification - The purified enzymes were quantified by the molar extinction coefficient for reduced *S. cerevisiae* Tsa1 and mutants ($\epsilon_{280} = 23,950 \text{ M}^{-1} \text{ cm}^{-1}$), except Tsa1^{Y77A} ($\epsilon_{280} = 22,460 \text{ M}^{-1} \text{ cm}^{-1}$) obtained using the ProtParam tool (<http://www.expasy.ch/tools/protparam.html>).

Protein reduction – Wild type and mutant proteins were initially reduced with 50 mM TCEP in 50 mM sodium phosphate buffer (pH 7.4) 50 mM NaCl, 100 μM diethylenetriaminepentaacetic acid (DTPA) and 1 mM sodium azide, for 30 minutes, at room temperature. In some cases TCEP was replaced by DTT (20 mM). After reduction, excess of TCEP or DTT was eliminated using a PD10 column (GE Healthcare).

Circular dichroism spectroscopy of Tsa1^{WT} and mutants carrying Thr44 or Arg123 substitutions

substitutions - The CD spectra of Tsa1^{WT} and mutant proteins were obtained using a 0.1 cm path length cuvette containing 10 µM of protein sample in 10 mM Tris buffer (pH 7.4) and 100 mM NaF. The assays were carried out at 25 °C in a Jasco J-810 spectropolarimeter (Jasco Inc.). Spectra were presented as an average of eight scans recorded from 190 to 260 nm. The content of secondary structures in each protein was estimated using the CDNN 2.1 software³².

Size-exclusion chromatography - Size-exclusion chromatography was performed by analytical HPLC (Jasco LC-2000Plus) equipped with a PU 2880 Plus injector and a PDA MD 2018 detector (Jasco). The samples (50 µM in 100 mM Tris-HCl at pH 7.4) were separated by a system containing a Phenomenex BioSep-SEC-S3000 column (7.8 × 300 mm, 5 µm, resolution range of 15 to 2000 kDa, Phenomenex, Inc., Torrance, California, USA) using a flow of 1.0 mL/min in 100 mM Tris-HCl buffer (pH 7.4) and 50 mM NaCl. The elution profile was monitored by absorbance ($\lambda = 280$ nm). Bovine thyroglobulin (670 kDa), bovine gamma globulin (158 kDa), ovalbumin (44 kDa), myoglobin (17 kDa) and vitamin B₁₂ (1.35 kDa) were used as molecular standards (Bio-Rad). The chromatograms were analyzed using Jasco BORWIN, version 1.50, software (Jasco). The enzymes were reduced or oxidized by treatment with 5 mM TCP or 1.2 molar excess of hydrogen peroxide, respectively, for 30 min/25°C.

Determination of Trx-linked peroxidase activity of Tsa1 mutants – Thioredoxin peroxidase activities were monitored by NADPH oxidation in a coupled assay²⁴. *S. cerevisiae* Tsa1^{WT} and mutants (1.0 µM) were incubated with Trx1 (2 µM), TrxR1 (0.3 µM) and NADPH (150 µM) in 50 mM HEPES buffer (pH 7.4) containing sodium azide (1mM) and DTPA (100 µM), at 30°C. Reactions were initiated by addition of hydrogen peroxide or cumene hydroperoxide

(CHP). All kinetic data were analyzed by non-linear regression using Michaelis-Menten equation (GraphPad Prism 5 software, GraphPad Software, Inc., San Diego).

Kinetics of Tsa1 oxidation using the intrinsic fluorescence of the enzyme - Reduced Tsa1^{WT}, Tsa1 mutants and Tsa2 enzymes (1 μM) in 40 mM sodium phosphate buffer (pH 7.4) were rapidly mixed with either H₂O₂ or CHP in excess in an Applied Photophysics SX-17MV stopped-flow spectrometer with a mixing time of approximately 2 ms. The reaction was followed by total fluorescence intensity decrease ($\lambda_{ex}=280$ nm) of the enzymes upon oxidation. Observed rate constants (k_{obs}) were determined by fitting the stopped-flow data to single exponential functions. The apparent second order rate constants of the oxidation of the enzymes by hydroperoxides (k_{ox}) were determined from the slope of k_{obs} values plotted against hydroperoxide concentrations.

Non-reducing SDS PAGE assays – To study reduction of peroxiredoxins by DTT and Trx1, wild-type Tsa1 and mutant proteins were previously reduced as described before and treated with hydrogen peroxide at 1.2 molar ratio in 50 mM sodium phosphate buffer (pH 7.4) containing 50 mM NaCl, 100 μM DTPA and 1 mM sodium azide. Next, the enzymes were reduced by increasing concentrations of DTT (10 μM to 10 mM) or Trx (2.5 to 25 μM) during 1 minute. The reaction was stopped with denaturing buffer (62.5 mM Tris-HCl, pH 6.8, containing 4% SDS and 10% glycerol) together with alkylation by 50 mM N-ethylmaleimide (NEM). Oxidized Tsa1^{WT} (intermolecular disulfide) runs as a dimer in non-reducing 12% SDS-PAGE, whereas reduced Tsa1^{WT} (dithiol) runs as a monomer in the same conditions. In order to evaluate the disulfide formation in the Tsa1^{WT} and mutants, the proteins were initially reduced as described above. The oxidation assays were performed using 10 μM of protein and 30 μM of H₂O₂, in 100 μL of final volume at room temperature, in 50 mM sodium phosphate

buffer (pH 7.4) containing NaCl 50 mM, 100 µM DTPA and 1 mM sodium azide. The reactions were stopped with 10 µL of denaturing buffer and 50 mM NEM to alkylate the thiols of the enzymes, precluding formation unspecific disulfide bonds (25) at the intervals of 0, 10, 30, 60, 90, 120, 300 and 600 seconds. Results were evaluated by non-reducing SDS-PAGE stained with Coomassie blue.

Analysis of PrxI/AhpC crystallographic structures - Analysis of available crystallographic structures and figures were performed using Pymol (<http://www.pymol.org>) and Discovery Studio 4.0. Distances and angles of non-conventional hydrogen bonds (CH-π interactions) in Prx structures were determined using Discovery Studio 4.0 software (<http://accelrys.com/products/discovery-studio>) according to (26).

The species abbreviation initials are given in italics and are as follows: *Escherichia coli* = AHPC_ECOLI (NCBI accession number: P0AE08.2); *Salmonella typhimurium* = AHPC_SALTY (P0A251.2); *Bacillus subtilis* = AHPC_BACSU (P80239.2); *Staphylococcus aureus* = AHPC_STAAS (Q6GC91.1); *Leishmania major* = PRX_LEISH (XP_001683326.1); *Trypanosoma cruzi* = PRX_TRYCRU (CAA06923.1); *Crithidia fasciculata* = TRYPCRIT (AAC72300.1); *Trypanosoma brucei* = TDX_TRYBR (Q26695.1); *Plasmodium vivax* = PRX_PLASM (XP_001616002.1); *Saccharomyces cerevisiae* = TSA1_YEAST (P34760.3) and TSA2_YEAST (Q04120.3); *Candida albicans* = TSA1_CANAL (Q9Y7F0.1); *Schizosaccharomyces pombe* = TSA1_SCHPO (O74887.1); *Larimichthys crocea* = PRX_LARIC (377656258); *Mus musculus* = PRX1_MOUSE (P35700.1); *Rattus norvegicus* = PRX1_RAT (Q63716.1); *Homo sapiens* = PRX1_HUMAN (Q06830.1), PRX2_HUMAN (P32119.5) and PRX4_HUMAN (Q13162.1). The green box denotes the catalytic triad Thr/Ser and the red box the Tyr/Phe.

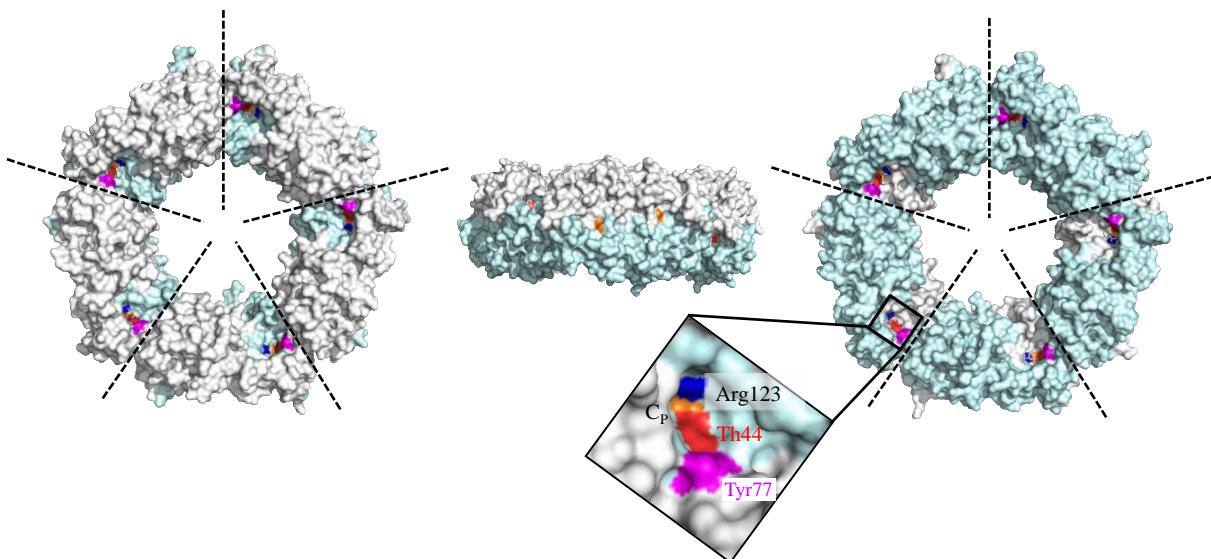

Figure 2. Position of the catalytic triad and Tyr⁷⁷ at *S. cerevisiae* Tsa1 molecular surface.
A monomer of obligate homodimer is colorized in white and the other in light blue. The dashed lines delimit the homodimers evidencing the D interface. The surface of the Arg¹²³ is represented in blue, the C_P in orange and Thr⁴⁴ in red. The Tyr⁷⁷ of the adjacent dimer is colorized in magenta.

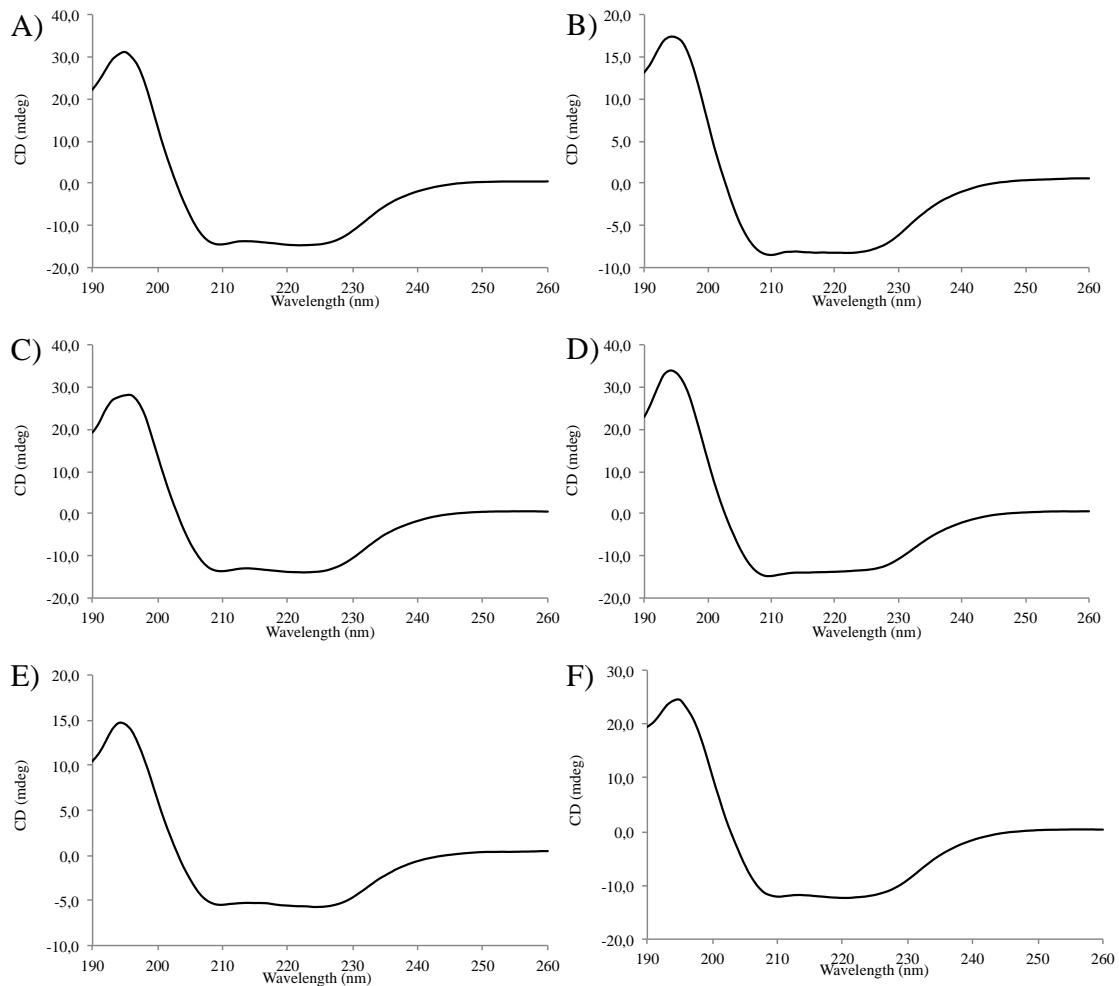

Figure 3. CD spectra of native samples of Tsa1^{WT} and mutants containing Thr⁴⁴ and Arg¹²³ substitutions. Spectra of the enzymes Tsa1^{WT} (A), Tsa1^{T44A} (B), Tsa1^{T44S} (C), Tsa1^{T44V} (D), Tsa1^{R123G} (E) and Tsa1^{R123K} (F). The proteins concentration used in experiments were 10 µM in 10 mM Tris buffer (pH 7.4) and 100 mM sodium fluoride. All spectra were recorded at 25°C and corrected against the buffer. The graphical representations are averages from eight consecutive scans.

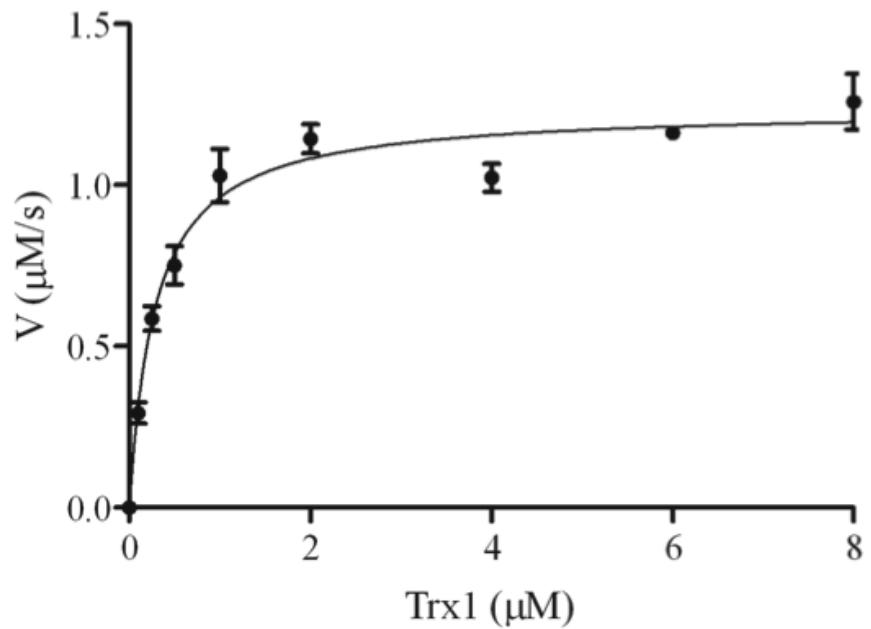

Figure 4. Dependence of Tsa1 peroxidase activity on thioredoxin concentration.
Hydrogen peroxide reduction rates were obtained in reaction mixtures containing NADPH (150 μM), TrxR (0.3 μM), Tsa1 (1 μM), in HEPES 50mM (pH=7.4) and sodium azide (1mM) and DTPA (100 μM), using variable concentrations Trx1 (0.1, 0.25, 0.5, 1.0, 2.0, 4.0, 6.0 and 8.0 μM). The reactions were performed at 30°C.

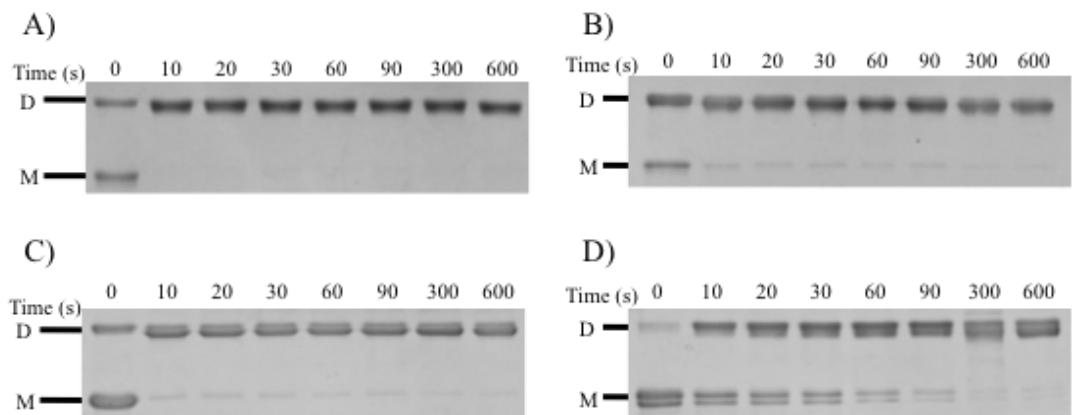

Figure 5. Monomer-dimer conversion of Tsa1 and mutants as a function of the time after oxidation by H_2O_2 . Tsa1^{WT} (A), Tsa1^{T44A} (B), Tsa1^{T44S} (C) and Tsa1^{T44V} (D) (10 μM) were treated with three equivalents of H_2O_2 . Proteins were previously reduced with 20 mM DTT for 30 minutes at room temperature and the excess was removed by gel filtration. Assays were performed at RT in 10 mM HEPES (pH 7.4), 100 μM DTPA, 1mM sodium azide. Reactions were stopped by the addition of buffer containing NEM (50 mM) 4% SDS, 10% glycerol, 62.5 mM Tris-HCl (pH 6.8) at the times indicated at the top of the figure. D = dimer and M = monomer.

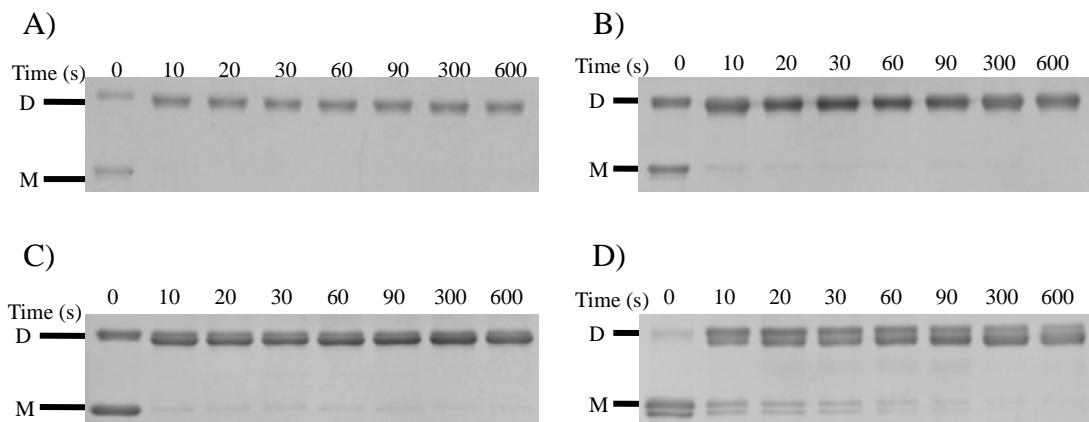

Figure 6. Monomer-dimer conversion of Tsa1 and mutants as a function of the time after oxidation by CHP. Reactions of Tsa1^{WT} (A) and mutants Tsa1^{T44A} (B), Tsa1^{T44S} (C) and Tsa1^{T44V} (D) (10 μ M) were treated with three equivalents of CHP. Proteins were previously reduced with 20 mM DTT for 30 minutes at room temperature and the excess was removed by gel filtration. Assays were performed at RT in 10 mM HEPES (pH 7.4), 100 μ M DTPA, 1mM sodium azide. Reactions were stopped by the addition of buffer containing NEM (50 mM) 4% SDS, 10% glycerol, 62.5 mM Tris-HCl (pH 6.8) at the times indicated at the top of the figure. D = dimer and M = monomer.

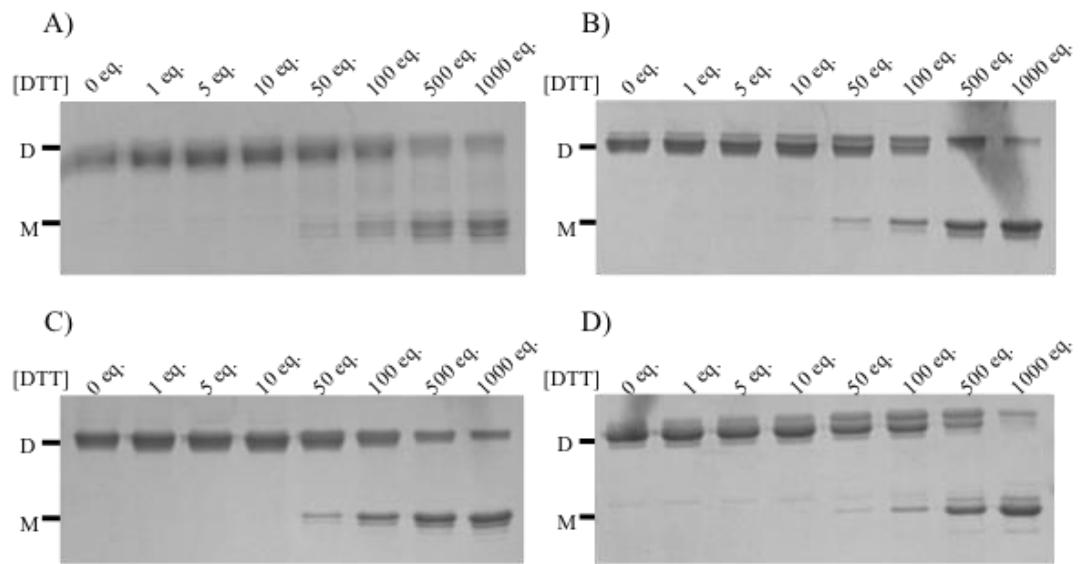

Figure 7. SDS-PAGE analysis of the reduction of Tsa1 and mutants by DTT. DTT-reduced Tsa1^{WT} (A), Tsa1^{T44A} (B), Tsa1^{T44S} (C) and Tsa1^{T44V} (D) (10 μ M) were previously oxidized with 1.2 eq. of hydrogen peroxide for 30 minutes at RT and reduced again for 1 minute at different concentrations of DTT as described in the upper part of the gels. Lane 1 contains the protein oxidized with 1.2 eq. of hydrogen peroxide and lanes 2-8 the product of reduction reaction with variable amounts of DTT. External left subtitles are: D = dimer and M = monomer.

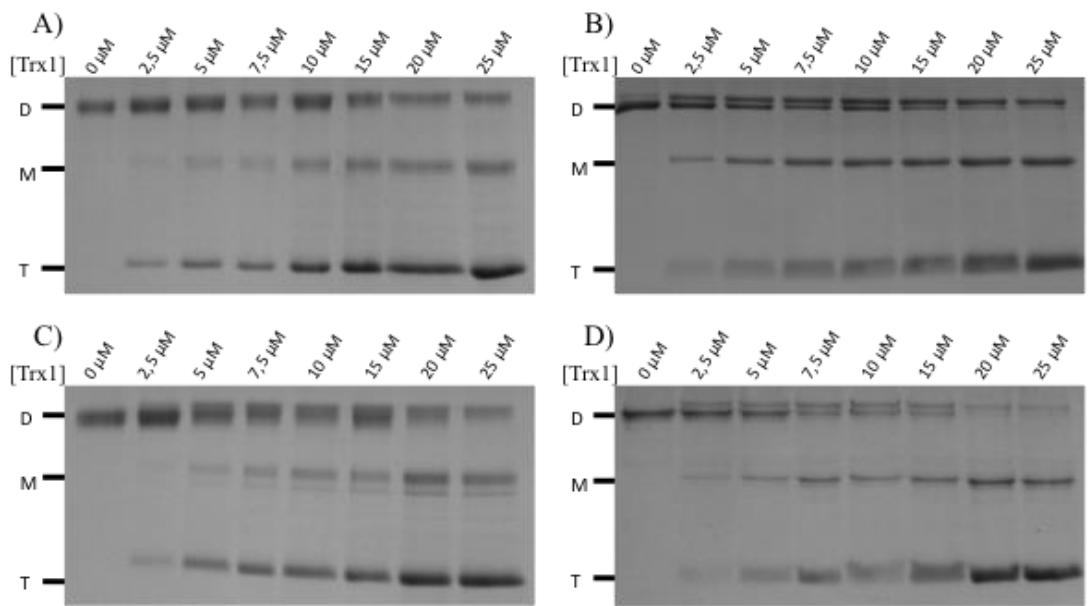

Figure 8. SDS-PAGE analysis of the reduction of Tsa1 and mutants by Trx1. Trx-reduced Tsa1^{WT} (A), Tsa1^{T44A} (B), Tsa1^{T44S} (C) and Tsa1^{T44V} (D) (10 μ M) were previously oxidized with 1.2 eq. of hydrogen peroxide for 30 minutes at RT and reduced again for 1 minute at different concentrations of Trx1 as described in the upper part of the gels. Lane 1 contains the protein oxidized with 1.2 eq hydrogen peroxide. D = dimer, M = monomer and T=thioredoxin.

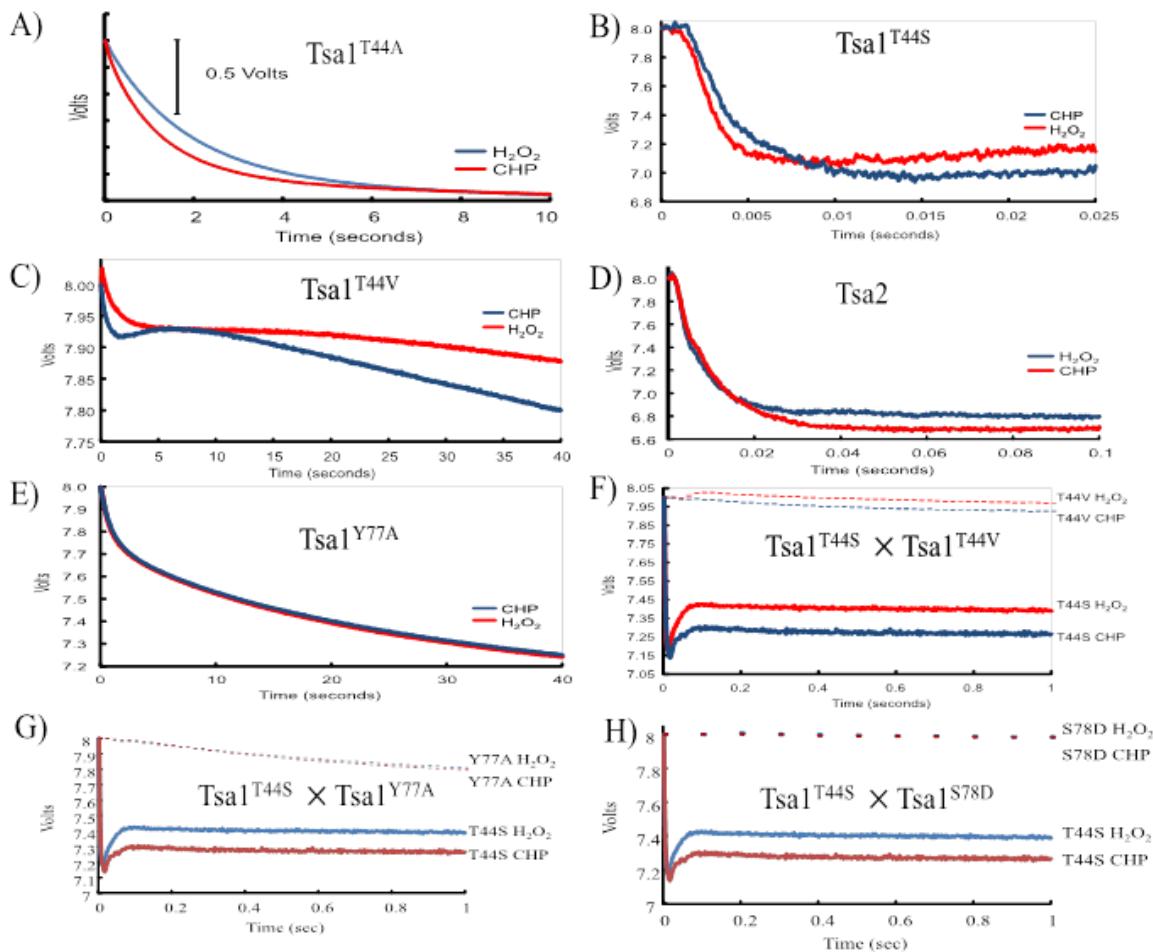

Figure 9. Representative examples of the rate of the reaction of Tsa1 mutants with hydrogen peroxide and cumene hydroperoxide. Samples were previously reduced with 20 mM DTT by 30 minutes at RT and the excess of reducing agent was removed by gel filtration. In the reaction, 20 μ M of H_2O_2 (red trace) or CHP (blue trace) was added to 1 μ M of Tsa1^{T44A} (A), Tsa1^{T44S} (B), Tsa1^{T44V} (C), Tsa2 (D), and Tsa1^{Y77A} (E). Comparative traces of Tsa1^{T44S} with Tsa1^{T44V} (F), Tsa1^{Y77A} (G) and Tsa1^{S78D} (H). The assays were performed in phosphate buffer (40 mM) pH = 7.4 at 25 °C. The rates were followed by the total fluorescence decay ($\lambda_{ex} = 280$ nm). Similar experiments were performed with different concentrations of hydrogen peroxide or CHP to determine k_{obs} and k_{ox} for each enzyme as described in the experimental procedures.

Abstract

L-asparaginase (L-asparagine amino hydrolase, E.C.3.5.1.1) is an enzyme clinically accepted as an antitumor agent to treat acute lymphoblastic leukemia and lymphosarcoma. It catalyzes L-asparagine (Asn) hydrolysis to L-aspartate and ammonia, and Asn effective depletion results in cytotoxicity to leukemic cells. Microbial L-asparaginase (ASNase) production has attracted considerable attention owing to its cost effectiveness and eco-friendliness. The focus of this review is to provide a thorough review on microbial ASNase production, with special emphasis to microbial producers, conditions of enzyme production, protein engineering, downstream processes, biochemical characteristics, enzyme stability, bioavailability, toxicity and allergy potential. Some issues are also highlighted that will have to be addressed to achieve better therapeutic results and less side effects of ASNase use in cancer treatment: (a) search for new sources of this enzyme to increase its availability as a drug; (b) production of new ASNases with improved pharmacodynamics, pharmacokinetics and toxicological profiles, and (c) improvement of ASNase production by recombinant microorganisms. In this regard, rational protein engineering, directed mutagenesis, metabolic flux analysis and optimization of purification protocols are expected to play a paramount role in the near future.

Introduction

L-asparaginase (ASNase) is an enzymatic drug and an essential component of the combination chemotherapy against diseases such as acute lymphoblastic leukemia (ALL), lymphosarcoma, Hodgkin's disease, acute myelogenous leukemia, acute myelomonocytic leukemia, chronic lymphocytic leukemia, reticulosarcoma and melanoma (Avramis & Tiwari, 2006; Kumar et al., 2014; Pui & Evans, 2006; Verna et al., 2007). This drug depletes L-asparagine (Asn) in blood, blocking protein synthesis and inhibiting DNA and RNA synthesis in cancer cells. As a result, cell

functions are impaired resulting in apoptosis (Bussolati et al., 1995).

Normal cells, however, are able to synthesize Asn and are less affected by its depletion by treatment with ASNase. Nonetheless, when used for long-term treatment, it may cause hypersensitivity leading to allergic reactions such as skin rashes, respiratory disorders, low blood pressure, sweating and loss of consciousness (Sarquis et al., 2004) as well as anaphylaxis (Verna et al., 2007). Different ASNase preparations from *Escherichia coli* [native (EcA) and PEGylated form] or *Erwinia chrysanthemi* [native form (ErA)] are available on the market (Tong et al., 2014). Additionally, a PEGylated recombinant *E. chrysanthemi*-derived ASNase is currently in Phase I clinical trials (<http://www.clinicaltrials.gov/show/NCT01551524>).

Mashburn & Wriston (1963) proved that purified *E. coli* ASNase exerted the same therapeutic effect as guinea pig serum (Jain et al., 2012), with the advantage of easier

121 production at lower cost (Schalk & Lavie, 2014). Asn has also
 122 shown to be a fundamental nutritional requirement for the
 123 *in vitro* growth of both Walker carcinosarcoma 256 and
 124 leukemic mice cells.

125 In recent years, there has been increased interest in
 126 ASNase use to treat ALL in adults, particularly young adults
 127 (Rytting, 2012). Out of the 4000 ALL cases diagnosed yearly
 128 in the USA, approximately two-thirds are children and
 129 adolescents, making ALL the most common cancer among
 130 this age group (Apostolidou et al., 2007; Pui & Evans, 2006).
 131 Long-term improvement in children was reported to be
 132 around 80%, and the overall survival rate 90%, while in adults
 133 these figures were 38% and 50%, respectively (De Bont et al.,
 134 2004; Pui & Howard, 2008). In recent decades, there has been
 135 considerable progress in leukemia treatment. However,
 136 because of issues related to the access to treatment, significant
 137 differences in survival are reported among populations.
 138 The five-year survival rate is 43% in the USA and Western
 139 Europe, 25% in Japan, 24% in South America, 19% in India,
 140 15% in Thailand, and 14% in sub-Saharan Africa. In areas
 141 with access to treatment, the five-year survival rate in
 142 children can reach 80% (Datasus, 2013; INCA, 2014).

143 ASNase is widely distributed in nature, it being found not
 144 only in microorganisms, but also in plants and in tissues
 145 (liver, pancreas, brain, ovary or testes, kidneys, spleen and
 146 lungs) of several animals like fishes, mammals and birds.
 147 However, microbes are a better source than animals or plants,
 148 considering their ability to grow easily on rather simple and
 149 inexpensive substrates. Furthermore, they offer easy optimization
 150 of culture conditions for enzyme bulk production,
 151 easy genetic modification to increase the yield, economically-viable
 152 extraction and purification, good stability and
 153 consistency (Thakur et al., 2014), coupled with the *ex situ*
 154 preservation.

155 Taking into account this scenario, the aim of this review is
 156 to provide a thorough review of microbial ASNase production.
 157 More specifically, it focuses on microorganisms,

181 conditions for enzyme production by either submerged or
 182 solid-state fermentation, applications, biochemical characteristics
 183 and manipulation, and downstream processes. 184

Upstream processing – ASNase production

Bacterial fermentation

188 Although several species of bacteria are reported to produce
 189 ASNase, *E. coli* and *E. chrysanthemi* are at present the main
 190 microbial agents for industrial-scale production. ASNases
 191 from these microorganisms have similar mode of action,
 192 antineoplastic activity and toxicity, but are serologically and
 193 biochemically distinct and have different pharmacokinetic
 194 profiles (Kumar & Sobha, 2012).

195 ASNase has mainly been produced by bacterial or fungal
 196 submerged fermentation (SF). Experimental evidence has
 197 shown that this production is greatly influenced by various
 198 factors such as type and concentration of carbon and nitrogen
 199 sources, pH, temperature, fermentation time, aeration and
 200 mainly the microbial agent (Basha et al., 2009; Gurunathan &
 201 Sahadevan, 2012; Zia et al., 2013).

202 A comprehensive review on the main aspects of ASNase
 203 production by bacterial SF was published by Kumar & Sobha
 204 (2012), to which the reader is invited to refer. Therefore, a
 205 simple list of the most significant bacteria able to extracellularly
 206 express ASNase is provided (Table 1) (Abdel-Fatah,
 207 1997; Abdel-Fatah et al., 1998; Alegre & Minim, 1993;
 208 Amena et al., 2010; Basha et al., 2009; Fisher & Wray, 2002;
 209 Geckil & Gencer, 2004; Geckil et al., 2006; Gladilina et al.,
 210 2009; Gunasekaran et al., 1995; Kenari et al., 2011; Koshi
 211 et al., 1997; Kotzia & Labrou, 2005; Kotzia & Labrou, 2007;
 212 Kumar et al., 2010; Lebedeva & Berezov, 1997; Lubkowski
 213 et al., 1996; Mahajan et al., 2012; Manna et al., 1995;
 214 Narayana et al., 2008; Nawaz et al., 1998; Pinheiro et al.,
 215 2001; Prakasham et al., 2007; Pritsa & Kyriakidis, 2001;
 216 Ramaiah & Chandramohan, 1992; Sidoruk et al., 2011; Sinha
 217 et al., 1991; Thenmozhi et al., 2011)

241 Members of the Enterobacteriaceae family are undoubtedly
 242 the best ASNase producers among the eubacteria. The addition
 243 of 6% *n*-dodecane under dissolved oxygen levels above 80%
 244 increased the *E. coli* cell concentration by 12.7% and ASNase
 245 activity (up to 60.80 IU/mL) by 21% (Wei & Liu, 1998).
 246 Among the other Enterobacteriaceae, when 10 g/L lactose or
 247 cheese whey was used as the carbon source for bench-scale
 248 batch cultivation of *Erwinia aroideae*, the addition of Asn and
 249 yeast extract or tryptone remarkably stimulated ASNase
 250 production (Alegre & Minim, 1993; Minim & Alegre, 1992).
 251 Also, the Gram-negative, rod-shaped bacterium *Enterobacter*
 252 *cloacae* was able to successfully utilize Asn either as the sole
 253 carbon and nitrogen source or in combination with L-fructose,
 254 D-galactose, sucrose or maltose and expressed ASNase intra-
 255 cellularly (Nawaz et al., 1998). ASNase production was also
 256 reported in *Enterobacter aerogenes* cultured on different
 257 carbon sources such as glucose, lactose, mannitol and glycerol
 258 (Geckil & Gencer, 2004; Geckil et al., 2005), but its activity
 259 was low (0.60 U/mL).

260 Another eubacterium able to express high levels of
 261 ASNase is *Pectobacterium carotovorum* MTIC 1428
 262 (Kumar et al., 2009); when grown under optimized conditions
 263 on a medium containing glucose, yeast extract, peptone and
 264 Asn, it exhibited a maximum activity of 15.39 U/mL (specific
 265 activity of 27.88 U/mg) after only 12 h along with the highest
 266 volumetric productivity (1.282 U/mL h) reported in the
 267 literature, to the best of our knowledge.

268 Although reports on ASNase production by filamentous
 269 bacteria are quite scarce, some of them, especially marine
 270 actinomycetes, were shown to be effective producers of this
 271 enzyme, among which is the thermophilic soil isolate S3 that
 272 displayed a ASNase activity as high as 49.20 U/mL at pH 7.5
 273 and 50 °C (Basha et al., 2009). These results open a new
 274 scenario in the search for more heat-resistant ASNases from
 275 thermophilic bacteria.

276 In recent years, solid-state fermentation (SSF) has emerged
 277 as a valid alternative to SF for the production of extracellular
 278

279 enzymes (Venil & Lakshmanaperumalsamy, 2009), because it
 280 allows employing agroindustrial wastes as nutrient sources
 281 and holds potential for the production of secondary metab-
 282 olites, especially in developing countries (Sangeetha et al.,
 283 2004). In comparison with SF, only a few reports are available
 284 on SSF for ASNase production, mainly using agroindustrial
 285 wastes, among which are soy bean meal (Abdel-Fattah &
 286 Olama, 2002; Basha et al., 2009; El-Bessoumy et al., 2004),
 287 rice bran (Venil & Lakshmanaperumalsamy, 2009), gram
 288 husk and coconut (Hymavathi et al., 2009). The most
 289 significant results found in the literature on SSF for ASNase
 290 production by bacteria are summarized in Table 2 (Abdel-
 291 Fattah & Olama, 2002; El-Bessoumy et al., 2004; Ghosh et al.,
 292 2013; Hymavathi et al., 2009; Venil & Lakshmanaperumalsamy,
 293 2009; Vuddaraju et al., 2010).

294 To provide only the most significant examples, optimiza-
 295 tion of SSF for ASNase production by *Pseudomonas*
 296 *aeruginosa* and *Serratia marcescens* has been reported by
 297 several authors. El-Bessoumy et al. (El-Bessoumy et al.,
 298 2004) obtained, under optimal conditions, ASNase activity of
 299 165.1 IU/mL (specific activity of 17.90 IU/mg) after 96 h of
 300 fermentation by *P. aeruginosa* 50071 in a medium with 40%
 301 moisture content containing 22 g/L soy bean meal, at pH 7.4
 302 and 37 °C. When 3.11% (w/v) casein hydrolyzate and 3.68%
 303 (w/v) corn steep liquor were added as supplementary nutrients
 304 to the same medium (20 g/L soy bean meal), but with higher
 305 moisture content (50%), this strain exhibited, under compar-
 306 able conditions (pH 7.0; 37 °C; 96 h), 38% lower specific
 307 activity (Abdel-Fattah & Olama, 2002), which confirms the
 308 influence of both environmental and nutritional conditions on
 309 SSF performance.

Fungal fermentation

310 Because all available ASNase therapeutic preparations are
 311 from prokaryotic sources, anaphylactic and other immuno-
 312 logical side effects as well as enzyme inactivation are
 313 frequent events. In this sense, the search for ASNase sources
 314

Table 2. Summary of fermentation conditions and results of L-asparaginase production by bacteria in SSF.

Microorganism	Substrates/conditions	L-asparaginase production	Reference
<i>P. aeruginosa</i> 50071	Soy bean meal 20 g/L; moisture content 50%; casein hydrolysate 3.11% (w/v); corn steep liquor 3.68% (w/v); pH 7.0; 37 °C; 96 h	11.15 IU/mg of proteins	(Abdel-Fattah & Olama 2002)
	Soy bean meal 22 g/L; moisture content 40%; pH 7.4; 37 °C; 96 h.	17.90 IU/mg of proteins; 165.1 IU/mL of crude extract	(El-Bessoumy et al. 2004)
<i>Bacillus circulans</i> MTCC 8574	Red gram husk; moisture content 99.5%; glucose 0.234% (w/w); Asn 0.248% (w/w); pH 7.0; 36.3 °C; 24 h.	2.322 U/gds	(Hymavathi et al. 2009)
<i>S. marcescens</i> SB08	Rice bran 10 g; moisture content 40%; Asn 0.01%; yeast extract 0.5%; pH 7.0; 30 °C; 36 h.	79.84 U/gds	(Venil & Lakshmanaperumalsamy 2009)
<i>S. marcescens</i> NCIM 2919	Sesame oil cake 40 g/L; moisture content 68.64%; glucose 3.1% (w/w); NaNO ₃ 1.01% (w/w); pH 7.0–7.5; 30 °C; 48 h.	110.8 U/gds	(Vuddaraju et al. 2010)
	Coconut oil cake 6 g; moisture content 40%; pH 6; 37 °C.	3.87 U/gds	(Ghosh et al. 2013)

300 Units are different because studies report values expressed in different units. IU, international unit; gds, grams of dried substrate.

from eukaryotic microorganisms can lead to enzymes with lower side effects to humans (Shrivastava et al., 2012). To achieve this purpose, the use of screening techniques is an important step of any prospecting process, which can be made based on function-driven analysis (e.g. color changes, fluorescence, presence of inhibition zones) or on sequence-driven analysis (e.g. gene detection by PCR, hybridization with specific probes). For both approaches, high- or medium-throughput screening has to be considered when a high number of biological materials or targets are the prospection focus (Sette et al., 2013).

Endophytic fungi have been reported as interesting ASNase producers. Theantana et al. (Theantana et al., 2007; Theantana et al., 2009), who investigated the major fungi present in Thailand medicinal plants, found the main producers of this enzyme in the genera *Colletotrichum*, *Eupenicillium*, *Fusarium*, *Penicillium* and *Talaromyces*. Marine environment, as well, appears to be a prolific source of ASNase-producing fungi. Thirunavukkarasu et al. (Thirunavukkarasu et al., 2011) found that this enzyme is secreted by seaweeds endophytes of the genera *Alternaria*, *Chaetomium*, *Cladosporium*, *Colletotrichum*, *Curvularia*, *Nigrospora*, *Paecilomyces*, *Phaeotrichoconis*, *Phoma* and *Pithomyces*. Sudha (Sudha, 2009) reported that 17 fungal strains recovered from mangrove soil were able to produce ASNase, and Sundaramoorthi et al. (Sundaramoorthi et al., 2012) selected five fungal strains isolated from different soils from Arabian Sea that exhibited the same activity.

A list of yeasts and filamentous fungi able to produce ASNase in SF is provided in Table 3 (Alhussaini, 2013; Gupta et al., 2009; Gurunathan & Sahadevan, 2012; Kil et al., 1995; Kumar & Manonmani, 2013; Lapmak et al., 2010; Raha et al., 1990; Ramakrishnan & Joseph, 1996; Sarquis et al., 2004; Shrivastava et al., 2012; Tippani & Sivadevuni, 2012; Zia et al., 2013).

Tippani & Sivadevuni (2012) detected ASNase activities of 404.0 and 376.0 IU/mL for *Fusarium semitectum* and *Fusarium moniliforme* using proline and glucose as nitrogen and carbon sources, respectively, while maximum production by *Fusarium oxysporum* (360.0 IU/mL) occurred with sodium nitrate. These results appear to be a clear proof of the leading role of nutritional factors in SF by fungi.

As far as the members of the *Aspergillus* genus are concerned, *Aspergillus niger* (Mishra, 2006), *Aspergillus terreus* and *Aspergillus tamari* (Sarquis et al., 2004) were shown to have great potential to produce ASNase. Limiting

the comparison only to the best results collected in the literature, *A. terreus* MTCC 1782 exhibited L-ASNase activity in the range 16.05–43.99 IU/mL when cultivated for 58–96 h in SF on Czapek–Dox medium (pH 6.0–6.3) supplemented with Asn, L-proline, glucose or sucrose at 30–35 °C and 140–160 rpm (Gurunathan & Sahadevan, 2012; Gurunathan & Renganathan, 2011). Lower ASNase activity was reported for *A. niger* (5.45 IU/mL) in the same medium (pH 6.5) supplemented with glucose and Asn at 35 °C and 120 rpm after 96 h (Zia et al., 2013) as well as for *A. flavus* (1.76 IU/mL) in a glucose-Asn medium (pH 4.5) supplemented with starch under static conditions at 30 °C (Patro et al., 2014).

As regards to other fungal genera, *Bipolaris* BR438 isolated from brown rice was reported by Lapmak et al. (Lapmak et al., 2010) to be the best ASNase producer among other genera, exhibiting ASNase activity of 6.30 IU/mL when cultivated in the Czapek–Dox medium containing 1% Asn and 0.4% glucose at 30 °C for 72 h.

Regarding SSF by fungi, several studies attempted to maximize ASNase production using different substrates and conditions. These results are summarized in Table 4 (Hosamani & Kaliwal, 2011; Mishra, 2006; Nair et al., 2013; Rani et al., 2012; Uppuluri & Reddy, 2009; Uppuluri et al., 2013). The best enzyme producers in SSF belong to the *Aspergillus* genus. Rani et al. (Rani et al., 2012) obtained maximum specific activity of 70.67 U/g with *Aspergillus* sp. KUFS20 using orange peel as a substrate, while *A. terreus* MTCC 1782 yielded no less than 253.0, 110.0 and 85.00 U/g on moistened pomegranate, wheat bran and coconut oil cake, respectively, after 72–120 h (Nair et al., 2013). Mishra (2006) reported, under aerobic conditions, a maximum ASNase specific activity of 40.90 U/g using *glycine max* bran with 70% moisture content and a mean particle size of 1205–1405 µm, after 96 h of SSF by *A. niger* at pH 6.5 and 30 °C.

The highest ASNase specific activity was reported for *A. niger* (344.0 U/g) cultivated in SSF on agro-wastes in a column bioreactor using sesame (black) oil cake as a substrate at 32 °C, 0.4 vvm aeration and 22 cm bed thickness (Uppuluri & Reddy, 2009; Uppuluri et al., 2013).

These results, taken together with those of SSF by bacteria, are very promising from the ASNase activity viewpoint; however, since SSF requires complex media, it appears to be still very far from satisfying the high purity requirements of ASNase for pharmaceutical and medical applications. Furthermore, in our opinion, the large availability of

Table 4. Summary of fermentation conditions and results of L-asparaginase production by filamentous fungi in SSF.

Microorganism	Substrates/conditions	L-asparaginase production	References

Units are different because studies report values expressed in different units. IU, international unit; gds, grams of dried substrate.

molecular biology tools makes the screening of fungal isoforms, rather than the cultivation of filamentous fungi, an interesting issue for future construction of a recombinant organism for ASNase production.

Downstream processing

Processes for producing therapeutic proteins have achieved substantial advances in the last decades. Nonetheless, purification processes deserve the same attention (Dutra-Molino et al., 2014). Downstream steps might reach 50–80% of the total production costs of proteins, and the best step combination can result in significant enhancement in terms of purification and process economy.

Protein precipitation

Separation by precipitation from an aqueous extract is the most traditional method to recover and purify biomolecules (Golunski et al., 2011). This method results in a temporary disruption of protein secondary and tertiary structures, leading to its precipitation. It is a technique easy to scale-up, with simple equipment requirements, low costs and possibility to use a large number of precipitants. Moreover, the precipitant agent can be recycled in the final process by distillation, evaporation or heat drying, thus reducing the environmental impact associated to its disposal.

ASNase recovery from different sources often employs precipitation. Several authors have purified ASNase up to apparent homogeneity by (NH₄)₂SO₄ precipitation (Amena et al., 2010; Basha et al., 2009; Gervais et al., 2013; Manna et al., 1995; Mishra, 2006; Moorthy et al., 2010). In general, partial purification starts with the addition of finely powdered (NH₄)₂SO₄ to the crude extract containing the enzyme up to saturation, causing ASNase precipitation. Salt concentration ranges from 35% to 100%, resulting in different yields depending on the ASNase source. Moorthy et al. (Moorthy et al., 2010) recovered up to 96.2% ASNase from *Bacillus* sp. grown on glucose, with purification fold of 10.9 after precipitation. Salt precipitation is usually followed by

centrifugation and column filtration to increase the purification yield. Production and purification of *Streptomyces gulbargensis* ASNase yielded 50.6%, with 1.8 purification fold. Purification was increased to 26.9-fold after precipitate was collected by centrifugation and dialyzed against buffer followed by Sepharcryl S-200 column filtration (Amena et al., 2010). Similar strategy was employed by El-Bessoumy et al. (El-Bessoumy et al., 2004) in the attempt to produce, isolate and purify ASNase from *P. aeruginosa* after SSF. Purification after (NH₄)₂SO₄ precipitation resulted in 5.2-fold purification and increased over five times after gel filtration through Sephadex G-100.

Other precipitant agents such as ethanol can also be successfully employed to pre-purify and concentrate the target biomolecule. Ethanol is widely produced in Brazil and worldwide (Golunski et al., 2011) and can be recycled after precipitation reducing the environmental impact.

Precipitation is one of the first steps in the downstream process and it is usually combined with traditional techniques to enhance biomolecules purification fold and process yield. Precipitation can also concentrate the target molecule reducing the volume for later stages (Glatz, 1990). Nonetheless, innovative techniques should be investigated aiming at faster and less expensive purification processes.

Liquid-liquid extraction

One interesting alternative to be exploited in separation science for biomolecules extraction/purification is liquid-liquid extraction (LLE) by aqueous two-phase systems (ATPS). LLE is defined as the removal of a solute from a liquid (or liquid mixture) phase when in contact with another immiscible or partially soluble liquid (or liquid mixture) where the component (solute) is preferentially soluble. Its partition can be improved using simple tools such as, for instance, the addition of affinity ligands (Albertsson, 1986; Lam et al., 2004). ATPS can be obtained when mixtures of water-soluble polymers are combined with another polymer or with certain inorganic salts above critical concentrations.

They can also be formed using other materials such as surfactants, block copolymers and ionic liquids. Several physicochemical properties influence protein partitioning in two-phase systems, namely isoelectric point, surface hydrophobicity and molar mass of system components. Also, partitioning depends on polymer or surfactant concentration, pH and salt addition (Albertsson, 1986).

Few attempts were made to employ ATPS to purify ASNase. Qin and Zhao (2003) described a combined strategy to release and separate ASNase from *E. coli* ATCC 11303 cells by aqueous two-phase micellar systems (ATPMS). Cells treated with 9.4% (w/v) K₂HPO₄ and 15% (w/v) Triton X-100 at 25 °C for 15–20 h released nearly 80% of the enzyme, while keeping whole. Considering the structure of *E. coli* cells and that ASNase is located in the periplasmic space, those authors proposed that Triton X-110 micelles might disrupt the outer membrane and cause the release of the enzyme from the periplasmic space. For this system (surfactant/phosphate/water), phase separation into a micelle-rich top phase and a salt-rich bottom phase was observed above critical micelle concentration. Most of the released enzyme was recovered in the bottom, phosphate-rich phase. In spite of the potential offered by ATPMS to release/purify ASNase, no data on purification factor or contaminants/whole cell partitioning behavior was reported.

Jian-Hang et al. (2007) proposed another strategy combining cell disruption by high-pressure homogenization and product capture by ATPMS for the extraction of intracellular ASNase from *E. coli*. They employed triblock copolymers of poly(propylene oxide) (PPO) and poly(ethylene oxide) (PEO), PEO–PPO–PEO, to form primary ATPS for enzyme purification. ASNase purification via this novel *in situ* process resulted in increased enzyme yield (from 52% to 73%) and specific activity (from 78.60 to 94.80 U/mg) compared with the conventional process, including cell disruption, centrifugal clarification and subsequent ATPMS.

ATPS still needs further investigation to be employed for commercial ASNase purification, but the results obtained with this technique already point to its potential. Furthermore, we believe that there is a need to further investigate ATPS composed of ionic liquids for ASNase purification, which seems to be a particularly promising alternative (Souza et al., 2015).

Chromatography

Intravenous enzymes preparations such as ASNase require high levels of purity, thus a sequence of purification processes is necessary. A high degree of enzyme purity is also important from the viewpoint of process control, but steps required for purification, in general, result in enzyme activity loss and increased final cost (Gräslund et al., 2008).

ASNase from *P. aeruginosa* 50071 obtained by SSF was purified by (NH₄)₂SO₄ fractionation, Sephadex G-100 gel filtration and CM-Sephadex C50 ionic exchange, and the specific activity increased from 17.90 (crude extract) to 1900 IU/mg (final preparation) (El-Bessoumy et al., 2004). A similar method was used by Singh et al. (2013) to purify extracellular ASNase from the protease-deficient *Bacillus aryabhattai* ITBHU02 strain. After (NH₄)₂SO₄ fractionation

and DEAE-Sepharose fast flow and Seralose CL-6B column chromatographic steps, the enzyme was 68.9-fold purified with specific activity of 680.47 U/mg. Warangkar and Khobragade (2010), who extracted and purified ASNase from *E. carotovora* by (NH₄)₂SO₄ fractionation (60–70%), followed by chromatographic steps using Sephadex G-100, CM cellulose and DEAE Sephadex, observed an increase in the enzyme specific activity from 1.36 to 1034 IU/mg, with a minimum mass loss and a final recovery of 36.5%.

Penicillium digitatum was also used to produce extracellular ASNase. After protein precipitation and desalting, gel filtration chromatography with Sephadex G-25, followed by Sephadex G-100, resulted in a 60.9-fold purification. Loureiro et al. (2012) purified ASNase from *Aspergillus* sp. by ion exchange chromatography (DEAE Sepharose) followed by gel filtration (Sephacryl S-200HR) at different flows, resulting in a 12% final yield and a 7.72 purification factor. An additional purification step by reapplying the pooled fraction to the same Sephadryl S-200HR column resulted in even lower yield (7.28%) with a purification factor of 10.7.

In recent work, ASNase has been obtained from the genus *Cladosporium*. Precipitation followed by DEAE cellulose ion exchange and subsequent size exclusion chromatography ensuring a final specific activity of 83.3 U/mg (Kumar & Manonmani, 2013).

This overview reveals that protocols for ASNase purification from different sources lead to different purification performances; therefore, any comparison is not straightforward. Nonetheless, one can see that gel filtration and ion-exchange chromatography are the most employed purification steps. They are often preceded by precipitation with (NH₄)₂SO₄ as a first pre-chromatographic step, which, in our opinion, may be replaced by some ATPS.

ASNase formulation

ASNase PEGylation

Conjugation of proteins with polyethylene glycol (PEG), or PEGylation, has become a well-established technology in the field of biopharmaceutical formulations to increase half-life. It reduces the urinary excretion of a biomolecule (Yang et al., 2004) as well as its enzymatic degradation due to the increased steric bulk (Veronese & Pasut, 2005). In addition, PEGylated bioproducts often exhibit reduced affinity for the target receptor compared with the native precursor, which can lead to a lower clearance by target-mediated clearance mechanisms. Finally, the addition of PEG moieties might enhance the immunological profile of a biomolecule by reducing its ability to raise antibodies (Mehvar, 2000).

Since PEG polymers are highly hydrated, with 2–3 water molecules per ethylene glycol unit, their hydrodynamic radii is approximately 5- to 10-fold greater than would be predicted based on their nominal molecular weight (Harris & Chess, 2003), underlying a dramatic increase in the effective molecular size of PEG–protein conjugates. PEG provides protein protection from proteases and peptidases, by impairing access of proteolytic enzymes. Conjugation with PEG creates a hydration shell surrounding proteins, whose size determines the degree of hydration and depends on PEG

721 structure, in that branched configuration has higher hydration
722 level compared with the random coil one (Tirosh et al., 1998).
723 Such a dynamic hydrated PEG shell is also responsible for
724 protection from proteolysis. Despite this, the high flexibility
725 of the PEG backbone chain usually enables high affinity
726 interactions between enzyme and substrate. Consequently,
727 PEGylated therapeutic proteins may retain efficacy while
728 acquiring greater stability in plasma (Fishburn, 2008).

729 PEG-ASNase was approved by the US Food and Drug
730 Administration in 1994 for the treatment of patients exhibiting
731 hypersensitivity to the native *E. coli* enzyme and in 2006
732 as a first-line treatment for patients with ALL. *E. coli*
733 ASNase, one of the first PEGylated proteins, was produced by
734 a random process coupling several 5 kDa PEG chains with the
735 enzyme surface. As a result, polydispersity is considerable in
736 PEG-ASNase formulations (Pasut et al., 2008).

737 Monomethoxylated PEG is generally used in protein
738 conjugation because its monofunctionality yields cleaner
739 chemistry. However, PEG diol impurities, with molecular
740 weight approximately twice that of the monofunctional
741 methoxy-PEG, are always formed in a percentage (1–10%)
742 that rises with PEG molecular weight, hence increasing the
743 polydispersity of conjugates (Veronese, 2001).

744 Enzyme PEGylation may be accompanied by loss of
745 biological activity of the conjugate compared with the native
746 enzyme, owing to sterical hindrance of the active site, which
747 may be somehow prevented by site-specific modifications
748 (Veronese & Pasut, 2005). In spite of these drawbacks, PEG-
749 ASNase formulations have longer half-life compared with
750 native enzymes (5 and 10 times longer than free *E. coli* and
751 *Erwinia* enzymes, respectively) (Dinndorf et al. 2007) and
752 increased thermostability (Soares et al., 2002). PEG-ASNase
753 activity in plasma is detectable 1 h after injection and
754 elimination half-life is 5.5–7.0 days, while native *E. coli*
755 and *Erwinia* ASNases have elimination half-lives of 26–30
756 and 16 h, respectively (Avramis & Panosyan, 2005).

757 After intramuscular injection, PEG-ASNase level gradually
758 increases, whereas that of Asn gradually falls over
759 several days. Intravenous injection of PEG-ASNase is better
760 tolerated and may lessen discomfort to patients and provide
761 immediate Asn depletion. Although ASNase dosage strongly
762 depends on its half-life, the effect of route of administration is
763 not so evident (Avramis & Panosyan, 2005).

764 In spite of increased half-life, decreased dosage and
765 frequency of PEG-ASNase, the degree to which PEGylation
766 reduces the enzyme immune response is unclear, and there are
767 reports where patients developed hypersensitivity to the
768 PEGylated form. Antibodies against PEG were found in
769 some patients with undetectable ASNase activity after
770 receiving PEG-ASNase and were proposed as the cause of
771 rapid clearance of conjugates and absence of enzyme activity
772 in serum (Pasut & Veronese, 2009).

773 Associated with the longer half-life of PEG-ASNase in
774 serum and, as a result of enzyme action, there is the risk of an
775 increase of ammonia blood concentrations to clinically
776 significant levels. Hyperammonemia, after ASNase therapy,
777 was first reported by Leonard and Kay in 1986 (Heitink-Pollé
778 et al., 2013), but the ASNases preparations they used (EcA
779 and ErA) had short half-life, and ammonia was rapidly
780 removed from circulation. Due to the longer PEG-ASNase

781 half-life, the ammonia concentration could not return to
782 normal levels between doses, and ammonia toxicity accumulated,
783 with the appearance of hyperammonemia symptoms
784 that disappeared after cessation of enzyme administration
785 (Heitink-Pollé et al., 2013). Based on this background, despite
786 the benefits of conjugating therapeutic proteins with PEG, in
787 our opinion, drug pharmacodynamics and pharmacokinetics
788 have to be better characterized to ensure therapeutics
789 efficiency of PEG-ASNases with minimal negative side
790 effects.

791 Freeze-dried formulations

792 Parenteral enzyme formulations must comply with their
793 specifications during long-term storage. Water-dispersed
794 enzymes, however, might be degraded through peptide bond
795 hydrolysis and deamination, among other reactions, which are
796 favored by a temperature increase (Singh et al., 2009).
797 ASNase is susceptible to these reactions, which reduce its
798 long-term or even short-term stability. For example, it was
799 shown that partial deamination of ErA and EcA changes their
800 isoelectric point and plasma half-life, although with no
801 changes in enzymatic activity (Gervais et al., 2013).
802

803 Freeze-drying can prevent most water-related reactions by
804 sublimating water from the frozen product under vacuum,
805 also allowing sterile drying without heating or chemical
806 sterilization. This process, however, suffers from other
807 undesired effects such as cold denaturation, freeze denatur-
808 ation and osmotic pressure increase due to dehydration and
809 cryoconcentration (Singh et al., 2009), whose relative
810 importance can be evaluated by splitting the process into
811 freezing and drying.
812

813 As regards the freezing process, ErA activity was lost up to
814 40% when the enzyme was subject to freeze–thaw cycling,
815 restored 24 h after freeze–thaw at –20 °C and partially
816 restored when the freezing temperature reached –40 °C.
817 Transient activity loss depends on the tetramer dissociation
818 rate (Gervais et al., 2013), whereas cleavage of dissociated
819 monomers leads to aggregation and permanent activity loss
820 (Jameel et al., 1997). Reconstituted EcA (Elspar®) was shown
821 to retain *in vitro* activity after cold storage for at least 14 days
822 (4 °C) and freezing (–20 °C) for at least 6 months, besides
823 resisting repeated freeze–thaw cycles (Wypij & Pondenis,
824 2013). Moreover, the presence of mannitol in Elspar®
825 formulation may contribute to prevent cold denaturation.
826

827 Freeze-drying without protectants is rarely an option for
828 proteins. Hellman et al. (1983) tested several protectants at
829 different concentrations, which had been submitted to the
830 same freeze-drying procedure as ErA. Glucose, mannose and
831 sorbitol showed 100% tetramer and activity retention after
832 reconstitution at pH 10, while 20% and 50% retentions were
833 observed in the absence of any protectant and in the presence
834 of mannose contained in commercial formulations, respect-
835 ively. Protein retention reached a maximum value when the
836 enzyme was freeze dried without protectants and reconsti-
837 tuted at pH 7.5. Conversely, Izutsu et al. (Izutsu et al., 1994)
838 observed 50% activity retention with the naked enzyme and
839 proposed mannitol as a good protectant under nat-
840 ural conditions, as long as the amorphous form is maintained.
841 Such discordance might be related to different

freeze-drying protocols employed by these research-groups, in that the former froze the product at -35°C for 24 h, while the latter quickly froze with liquid nitrogen.

The collapse temperature is an essential parameter for freeze-drying; formulations must in fact be dried below their collapse temperature to maintain stability, easy reconstitution and dry cake form. Adams and Ramsay (Adams & Ramsay, 1996) characterized ErA formulations with a variety of protectants in terms of collapse temperature, cake structure and activity/tetramer retention. Lactose was shown to be the most suitable protectant among those tested, together with lactose/mannitol combination. These authors performed a cycle optimization to reduce the drying time, based on the collapse temperature. Lactose effectiveness as a protectant during ErA freeze-drying confirmed the results of a previous study that demonstrated the potential of other disaccharides as enzyme stabilizers such as trehalose and maltose (Adams & Irons, 1993).

Lyoprotection mechanisms are not fully elucidated. Based on the current hypothesis that protectants substitute water in protein hydration shell, Ward et al. (1999) proposed that each highly polar residue of ASNase requires one molecule of protectant, and this way they were able to estimate sugar concentration, but failed to predict PEG amount.

Instead of adding protectants, it is possible to conjugate them to improve thermostability, among other properties. For instance, PEGylated EcA activity was entirely recovered when reconstituted after freeze-drying (Soares et al., 2002). EcA conjugation with inulin, on the other hand, led to improvement in freeze-thawing resistance with no significant change in freeze-drying (Tabandeh & Aminlari, 2009).

Literature on EcA freeze-drying is scarce and outdated, while ErA is more explored. Papers are generally broken down into formulation screening or process parameters, with large disparities in freeze-drying methodology. Patents were deposited but, for obvious reasons, information is not straightforward. So far, no model is adequate enough to predict freeze-drying behavior of protein solutions; therefore, empirical testing is still needed to obtain an adequate formulation.

Structural features, undesirable characteristics and protein engineering of bacterial ASNases

Despite being a widely used drug, ASNase possesses a secondary L-glutaminase activity (GLNase), and several side effects are associated with ASNase-based treatments, including immunological reactions, hepatotoxicity, neurotoxicity, coagulation abnormalities, among others. Additionally, its administration to patients often results in a rapid decay of circulating ASNase levels, leading to high administration frequency. Determination of crystallographic structure of several ASNases has assisted decisively in a better elucidation of the enzyme features and the catalytic process. Moreover, these data have currently enabled approaches involving rational enzyme engineering based on structural data and *in silico* methods, aiming to obtain more efficient and specific bacterial ASNases.

Enzyme structure and catalytic mechanism

EcA was the first bacterial ASNase whose high-resolution crystallographic structure was determined (Swain et al., 1993). Structural studies revealed a well-organized homotetrameric enzyme, with each monomer containing ~ 330 amino acids arranged in two domains (N- and C-terminal), both belonging to the α/β class. The N-terminal domain comprises the residues 1–190 and is connected to the smaller C-terminal domain (213–326) by a large linker (191–212) (Figure 1A). Monomers are able to associate tightly with each other forming intimate dimers characterized by an extensive interface between the subunits that are held together by several interactions, mainly van der Waals and electrostatic interactions (Figure 1B). Finally, the association of two dimers results in the tetrameric biological unit, which is kept together by molecular interactions similar to those found in homodimers (Figure 1C) (Jaskolski et al., 2001; Swain et al., 1993). Several macromolecular ASNase structures are available at Protein Data Bank (PDB) (<http://www.rcsb.org>), including ErA (Lubkowski et al., 2003; Sanches et al., 2003), which shares high structural homology with the *E. coli* counterpart (r.m.s.d. = 0.89) (Figure 1D).

ASNases active sites are located at the interface of intimate dimers, with each intimate dimer containing two active site pockets formed by amino acids from both subunits (Palm et al., 1996; Swain et al., 1993). Structural and functional studies revealed that the so-called catalytic triad composed of three polar amino acids, namely Thr-Lys-Asp (Thr⁸⁹, Lys¹⁶² and Asp⁹⁰ in EcA), is essential for enzyme activity (Jaskolski et al., 2001).

Examination of ASNase structure with ligand molecules in the active site revealed the formation of an intricate hydrogen network with ligands (Figure 2A and B) and disclosed two additional residues of importance for the catalytic mechanism (Thr¹² and Tyr²⁵ in EcA) (Michalska & Jaskolski, 2006). These residues are located in a large loop (amino acids 10–32 in EcA) that operates as a lid for the active site, probably assisting the correct substrate binding and thus favoring catalysis (Figure 2C and D).

Immunological side effects and enzyme instability

ASNase administration can promote a number of harmful side effects including immunological responses, ranging from allergic reactions to fatal anaphylactic shock, coagulation disorders, pancreatitis, hyperglycemia, hepatotoxicity and protein synthesis inhibition (Rizzari et al., 2013). As far as the immunological side effects are concerned, the decay of ASNase antitumoral activity is directly associated with the production of ASNase antibodies by the patient, which leads to the drug clearance from the bloodstream and reduces the treatment efficacy. In this respect, early studies have shown high circulating levels of ASNase by ELISA with low enzyme activity, which was initially attributed to ASNase denaturation (Asselin et al., 1993). However, more recent studies suggest that ASNase clearance may be a result of protease cleavage (Offman et al., 2011). Protein stability and immunogenic effects are apparently closely related. The proteolytic cleavage of ASNase may be responsible for additional epitopes exposure, which are involved in the patients' immune

Figure 1. Structural features of bacterial ASNase. (A) Cartoon representation of ASNase monomer from *E. coli*, composed by the N-terminal and C-terminal domains connected by a large loop. (B) Molecular surface of intimate dimer of EcA with one monomer colored in blue and the other in light gray. (C) Homotetrameric quaternary structure of EcA. Each monomer is represented by a different color (A, dark blue; B, yellow; C, light gray; D, red). The enzyme cartoon representation is depicted inside the molecular surface. (D) Superposition of crystallographic structures of ASNases from *E. coli* (blue) and *E. chrysanthemi* (green). Graphic models were generated by PyMOL software (<http://www.pymol.org>) using the coordinates 3ECA (*E. coli*) and 107J (*E. chrysanthemi*) from the PDB (<http://www.rcsb.org>).

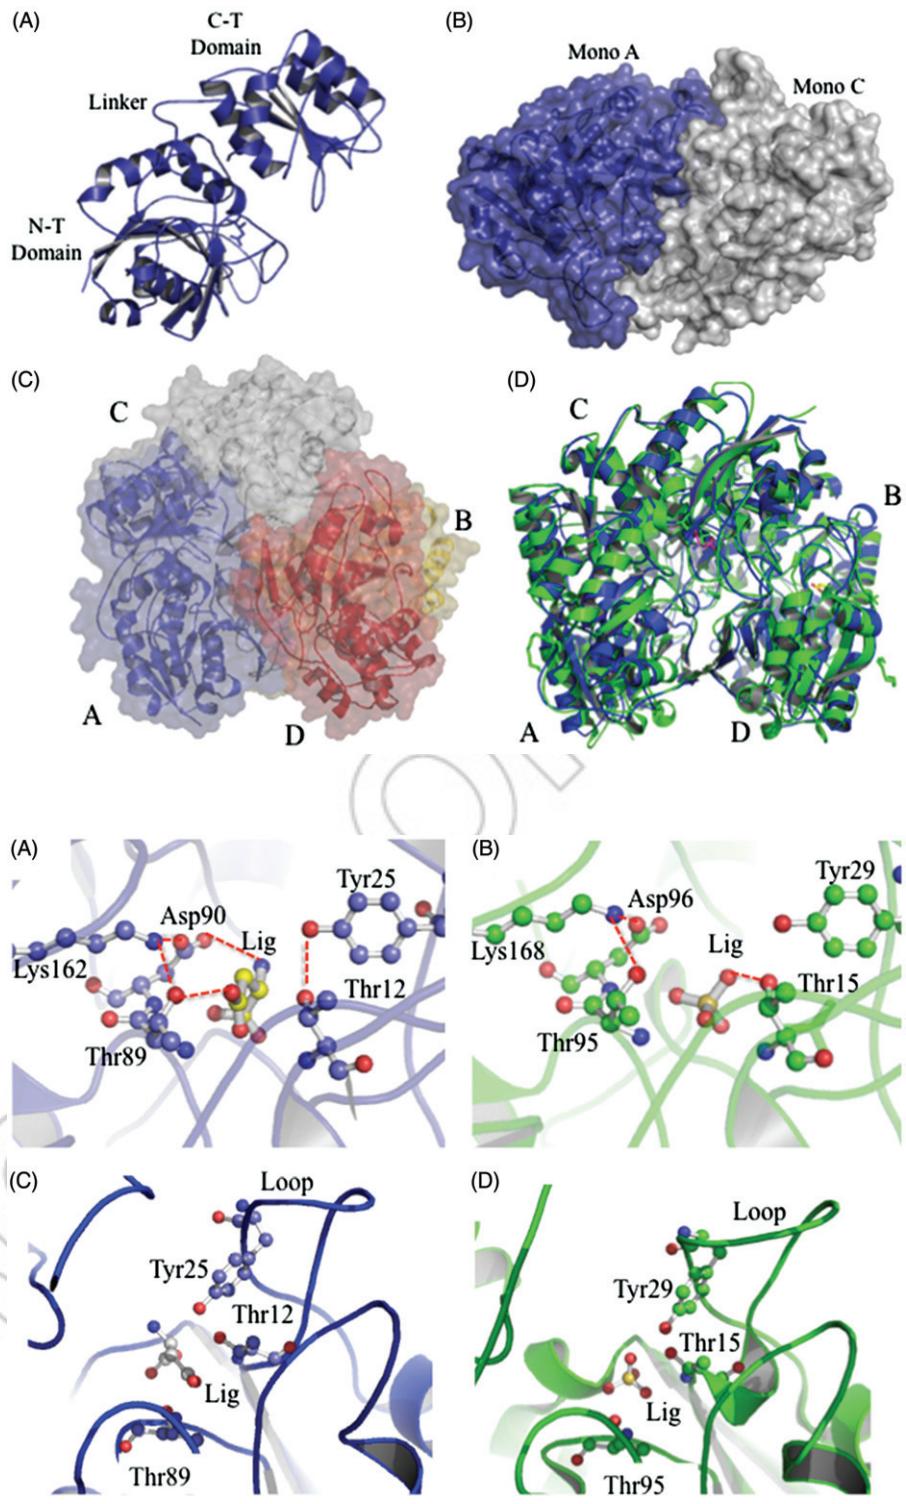

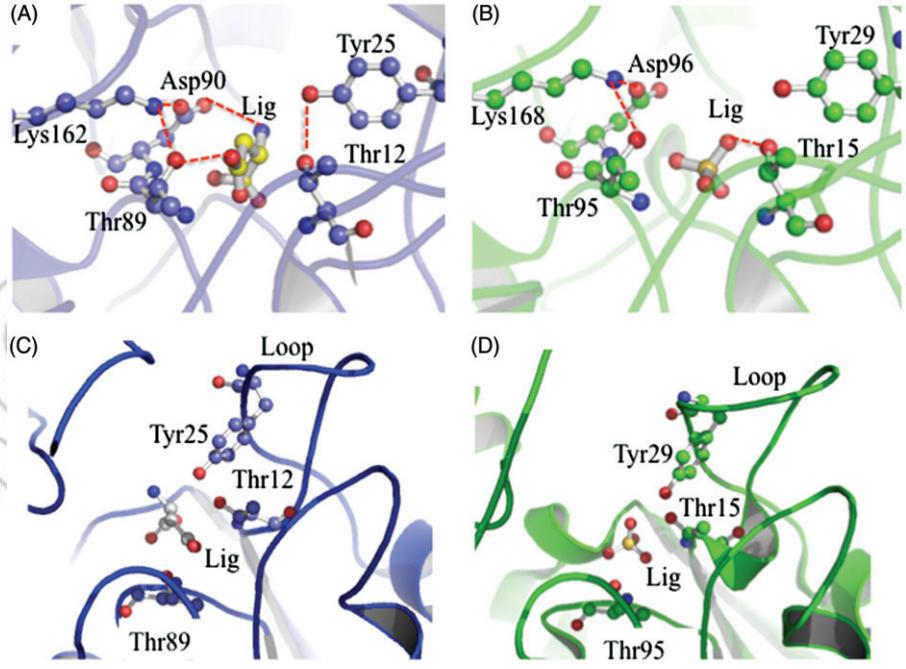

Figure 2. ASNases active site pocket structural features and ligand binding. The active site regions of EcA (blue) (A) and ErA (green) (B) reveal extensive structural homology of amino acids involved in catalysis (Thr¹², Tyr²⁵, Thr⁸⁹, Asp⁹⁰ and Lys¹⁶² in *E. coli*, and Thr¹⁵, Tyr²⁹, Thr⁹⁵, Asp⁹⁶ and Lys¹⁶⁸ in *E. chrysanthemi*). Detail of the active site region of EcA (C) and ErA (D) showing the position of the loop at the entrance of active site pocket.

Representations are in cartoon and catalytic amino acids are represented by ball and stick and colored by CPK (O, red; N, blue; C, same color of the enzyme). For the ligands aspartate (C) and SO₄ (D) carbons are in yellow, sulfur in orange, oxygens in red and nitrogen in blue. Graphic models were generated by PyMOL software (<http://www.pymol.org>) using the coordinates 3ECA (*E. coli*) and 107J (*E. chrysanthemi*) from the PDB (<http://www.rcsb.org>).

response (Offman et al., 2011; Patel et al., 2009). In this respect, cysteine proteases such as asparagine endopeptidase (AEP) and cathepsin B are able to hydrolyze bacterial ASNase.

ASNase antibody production has been observed in 60% of patients treated with EcA. ASNase hypersensitivity clinical symptoms include anaphylaxis, pains, angioedema, hives, rash and pruritus. Hypersensitivity occurs more frequently when the treatment is interrupted or discontinued, with children presenting less hypersensitivity and antibody

production when compared to adolescents and adults (Pieters et al., 2011; Shrivastava et al., 2015).

Replacement or modification of ASNases to mitigate the immune side effects

The immunological side effects of ASNases can be partially minimized using enzymes from different bacteria (e.g. replacing EcA for ErA) (Avramis & Tiwari, 2006). In addition, new experimental protocols of enzyme

1081 encapsulation into erythrocytes or entrapment into liposomes
 1082 showed lower side effects (Agrawal et al., 2013; Kwon et al.,
 1083 2009; Patel et al., 2009).

1084 As mentioned before, three ASNase formulations are used
 1085 to treat ALL and other lymphoid malignancies, namely EcA,
 1086 ErA and PEGylated EcA. Native EcA is the most commonly
 1087 used worldwide and considered first-line therapy in Europe,
 1088 with usual dosage of 6000 IU/m² thrice a week and elimination
 1089 half-life of 26–30 h. PEGylated EcA, which is the first-
 1090 line therapy in USA, has a half-life (5.5–7.0 days) five times
 1091 longer than native EcA and, consequently, its dosage is lower
 1092 (2000–2500 IU/m² every 2 or 4 weeks). ErA has been used at
 1093 a dosage of 6000 IU/m² thrice a week as a therapeutic option
 1094 in patients with side effects from EcA, because it elicits lower
 1095 immunological response and induces minor coagulation
 1096 disorders. The main disadvantage of ErA is its half-life of
 1097 only 16 h (Shrivastava et al., 2015).

1099 Side effects and GLNase activity

1100 An important side effect of ASNase treatment is related to the
 1101 nonspecific ASNase amidohydrolase activity. Patients treated
 1102 with bacterial enzymes also exhibit low levels of L-glutamine
 1103 (Gln) in the bloodstream, resulting in decreased levels of
 1104 protein synthesis (Offman et al., 2011). Despite the signifi-
 1105 cantly lower k_m of ASNase amidohydrolase activity for Asn
 1106 (30-fold lower in EcA) (Avramis & Tiwari, 2006), Gln
 1107 represents 50% of all free amino acids in the body being an
 1108 important nitrogen source (Ramya et al., 2012). The general
 1109 effect of lowering protein synthesis is directly associated with
 1110 several side effects, among which are as immunosuppression,
 1111 thromboembolism and neurological disorders (Kafkewitz &
 1112 Bendich, 1983; Villa et al., 1986).

1113 In spite of toxicity, Offman et al. (2011) demonstrated,
 1114 using molecular dynamics and site direct mutagenesis, that
 1115 GLNase activity of EcA is necessary for antitumor effect, and
 1116 similar results were observed for *Helicobacter pylori* ASNase
 1117 (HpASNase) (Parmentier et al., 2015). However, GLNase
 1118 activity of EcA was shown be irrelevant for antitumor effect
 1119 against cell lines that do not express asparagine synthetase
 1120 (ASNS), but required in cell lines with high ASNS levels
 1121 (Chan et al., 2014).

1123 Resistance to ASNase treatment

1125 Many patients are refractory to treatment with ASNases,
 1126 which is ultimately related to differences in genetic back-
 1127 ground and gene expression profile, including especially
 1128 NF-κB related genes. This indicates very complex genetic,
 1129 biochemical and cellular relationships involved in ASNase
 1130 resistance mechanism (Chien et al., 2015; Holleman et al.,
 1131 2004). Several studies demonstrated that ASNase resistance is
 1132 associated to ASNS up-regulation in ALL cells that are
 1133 refractory to bacterial ASNase treatment (Chan et al., 2014;
 1134 Chien et al., 2015). Conversely, the decrease of *asns* mRNA
 1135 expression levels enhances the sensitivity of HL-60 cells to
 1136 EcA treatment (Hashimoto et al., 2009).

1137 Studies with ASNS inhibitors also indicate the role of this
 1138 enzyme in the resistance to ASNase treatment. For example,
 1139 analogues of adenylated sulfoximine, an intermediate of
 1140 ASNS catalytic mechanism, are able to enhance the *in vitro*

1141 cytotoxicity of bacterial ASNases to resistant cell lines
 1142 (MOLT-4) (Gutierrez et al., 2006; Ikeuchi et al., 2009;
 1143 Ikeuchi et al., 2012).

1144 As discussed above, recently some authors have argued
 1145 that glutaminase activity of ASNases is fundamental for
 1146 cytotoxicity against several types of ALL cancer cells (Chan
 1147 et al., 2014; Chien et al., 2015), so the Gln intracellular levels
 1148 may be also important for treatment efficacy. In this context,
 1149 among several drugs used in combination with ASNases are
 1150 the glucocorticosteroids, stimulators of glutamine synthetase
 1151 (GLNS) expression (Gaynon & Carrel, 1999). Despite the
 1152 lack of studies on the effects of GLNS in ALL cells, inhibition
 1153 of Gln uptake was recently suggested to play a role in the
 1154 treatment of acute myeloid leukemia, since bacterial ASNase
 1155 up-regulates GLNS expression. Additionally, GLNS inhibi-
 1156 tion by methionine-L-sulfoximine in six different human
 1157 sarcoma cell lines with distinct sensitivity to ASNase
 1158 increased cytotoxicity (Tardito et al., 2007). Nonetheless,
 1159 more studies on GLNase activity of ASNases are necessary
 1160 to verify the molecular mechanisms involved in enzyme
 1161 regulation and cancer cell proliferation.

1163 Mutational studies and rational enzyme engineering

1165 Several mutational approaches were performed in ASNase
 1166 aiming to investigate aspects such as catalysis, substrate
 1167 binding, turnover and affinity, antigenicity and oligomeriza-
 1168 tion, among others. Table 5 summarizes the structural effects
 1169 of amino acids mutations in EcA (Aung et al., 2000; Borek
 1170 et al., 2014; Chan et al., 2014; Derst et al., 1992; Derst et al.,
 1171 1994; Derst et al., 2000; Harms et al., 1991; Jaskolski et al.,
 1172 2001; Jianhua et al., 2006; Mehta et al., 2014; Offman
 1173 et al., 2011; Palm et al., 1996; Verma et al., 2014; Wehner
 1174 et al., 1992).

1175 Excluding the pioneering studies involving covalent
 1176 modifications by inhibitors, peptide sequencing and other
 1177 techniques to identify amino acids involved in catalysis
 1178 (Harms et al., 1991; Wehner et al., 1992), the vast majority of
 1179 the site mutagenesis approaches were in fact performed after
 1180 the determination of EcA crystallographic structures. These
 1181 include structures showing ligands at the active site pocket
 1182 (Jaskolski et al., 2001), demonstrating the importance of
 1183 protein structure knowledge to rationally evaluate the amino
 1184 acids involved in substrate binding and catalysis as well to
 1185 plan replacements strategies.

1186 The amino acids substitutions that affect the kinetic
 1187 parameters of bacterial ASNases are concentrated, close to
 1188 the active site, in the intimate dimer interface (Figure 3A and
 1189 B). However, there is a lack of mutational studies on the dimer
 1190 complementary region, which is also part of the active site
 1191 pocket (Figure 3C and D). This observation is important,
 1192 since the active site volume is closely related to substrate(s)
 1193 binding, aspects that will be addressed later.

1194 The molecular surface mapping of amino acids substitu-
 1195 tions that cause alterations of enzyme stability reveals that
 1196 several amino acids are located at the enzyme surface, some
 1197 of them between the dimers (Asn²⁴, Asp¹³⁸ and Tyr²⁵⁰) or
 1198 tetramer contacts (Asn³⁷, Asn¹²⁴, Lys¹³⁹, Tyr¹⁸¹ and Lys²⁰⁷)
 1199 (Figure 4). Rational efforts were also performed aiming to
 1200 enhance enzyme stability and half-life. Replacement of Asn²⁴

Table 5. Summary of the amino acid mutations and the functional/structural effects on *E. coli* L-asparaginase.

Amino acid	Substitution(s)	Functional and or structural effects	Reference
G11	V11 or L11	Catalysis almost abolished	(Derst et al. 2000)
T12	A12	ASNase activity reduced to 0.01%	(Harms et al. 1991)
T12	A12	ASNase activity reduced to 0.04%	(Derst et al. 1992)
T12	S12	Normal activity but altered substrate specificity	
N24	G24	Decrease of ASNase and GLNase activities	(Offman et al. 2011)
N24	A24 or T24	AEP resistant enzyme	
N24/R195	A24/S195	Decay of ASNase activity/slight decrease of GLNase activity	
N24/R195	T24/S195	Abolishment of ASNase activity/slight decrease of GLNase activity	
N24/Y250	A24/L250	Abolishment of ASNase activity/slight decrease of GLNase activity	
N24/Y250	T24/L250	Abolishment of ASNase activity/slight decrease of GLNase activity	
Y25	F25	High decrease of GLNase activity	(Jaskólski et al. 2001)
Y25	A, H or F	ASNase activity reduced to 0.1–0.2%	(Derst et al. 1994)
V27	L27 or M27	Reduction in K_m values/moderate reduction of k_{cat} for Asn	(Derst et al. 2000)
G57	A57	Little effect on substrate specificity/reduction of activity with AHA, Asn and Gln	
G57	V57 or L57	Strong reduction of k_{cat} for all substrates/low alteration in substrate specificity	
Q59	G59 or A59	Strong increase in K_m for AHA/Increase of binding constants for aspartate/Interference in GLNase activity to larger extent than the turnover of AHA or Asn.	
Q59	E59	Reduction in k_{cat} for aspartic β -hydroxamate (AHA), Asn and Gln to about 10% of the wild-type/No differences between ASNase and GLNase activities	
Q59	L59	High decrease of GLNase activity/slight effect on ASNase	(Chan et al. 2014)
Q59	N59	Decrease (~80%) of GLNase and ASNase activities	
Q59	H59	Decrease (~50%) of GLNase and ASNase activities	
Q59	L, F, C, T, S, Y, W, V, I, A, M, P, G, R or K	High decrease of GLNase activity	
W66	Y66	More effective killing of ALL cells/Induction of apoptosis in lymphocytes derived from ALL patients/Rapid depletion of Asn/down-regulation of the transcription of asparagine synthase	(Mehta et al. 2014)
W66/Y25	Y66/W25	Decrease of k_{cat} for Asn/reduction of active site loop movement	(Aung et al. 2000)
W66/Y176	Y66/W176	Resistance to chemical denaturation/Increase of V_{max}/K_m for AHA	(Verma et al. 2014)
W66/Y181	Y66/W181	Higher susceptibility to chemical and thermal denaturation	
H87	A87, L87, K87	No substantial changes of K_m ; Moderate decrease of k_{cat} for Asn	(Wehner et al. 1992)
G88	A88 or I88	Asn catalysis almost abolished	(Derst et al. 2000)
T89	V89	Aspartate aspartyl moiety was found to be covalently bound to Thr-12	(Palm et al. 1996)
D90	E90	Decrease of k_{cat} and increase of K_m for Asn	(Borek et al. 2014)
T119	A119	Decrease of Asn activity with no marked effect on substrate binding	(Derst et al. 1992)
S122	A122	No effect	
Y176	F176	More effective killing ALL cells/Induction of apoptosis in lymphocytes derived from ALL patients/rapid depletion of Asn and down-regulation of ASNS transcription/decrease of GLNase activity/Increase of V_{max}/K_m for AHA	(Mehta et al. 2014, Verma et al. 2014)
Y176	S176	Decrease of GLNase activity/Increase of V_{max}/K_m for AHA	
Y181	S181 or C181	Instability of tetramer	(Derst et al. 1994)
H183	L193	Sensitivity to urea	(Wehner et al. 1992)
R195/K196/H197	A195/A196/A197	Reduction in antigenicity	(Jianhua et al. 2006)
H197	L197	No substantial changes of K_m ; moderate decrease of k_{cat}	(Wehner et al. 1992)
N248	D248 or E248	Reduction of k_{cat} for Asn	(Derst et al. 2000)
N248	A248	Loss of transition state stabilization of Gln hydrolysis twice as high as that for Asn and more than three times higher than for AHA	
N248	G, D, Q or E	Moderate reduction of maximum velocity of Asn hydrolysis/Strong impairment of Gln turnover.	
Y250	F250	No effect	(Derst et al. 1994)
K288	R288	Decrease of GLNase activity	(Mehta et al. 2014)
K288/Y176	S288/F176

		Instability of tetramer	

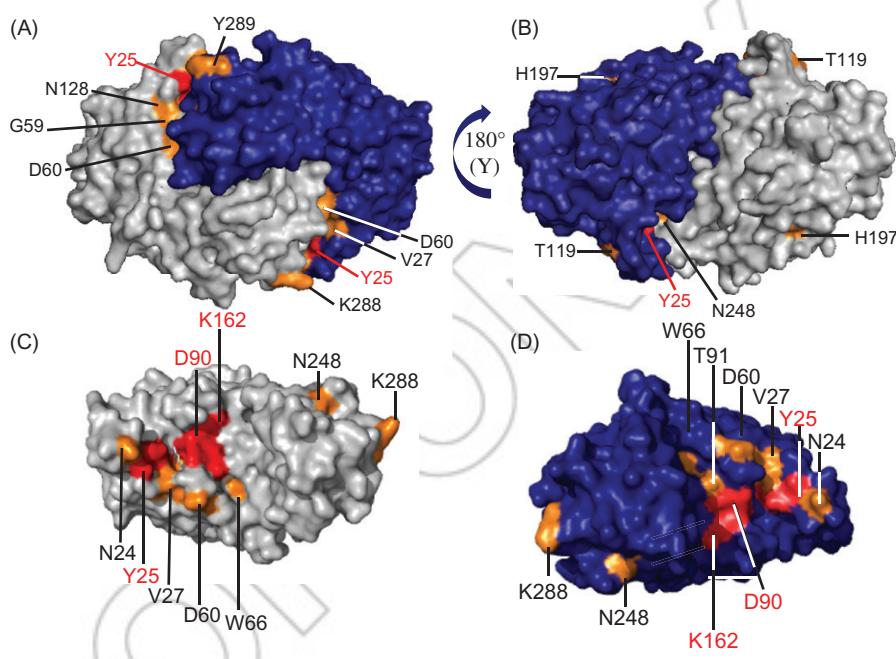

ASNase, L-asparaginase; GLNase, L-glutaminase; Asn, L-asparagine.

Figure 3. *E. coli* ASNase surface structural representations of mutational approaches influencing enzyme activity. (A and B) EcA dimer with one monomer colored in gray and the other in dark blue, showing the positions of amino acids whose substitutions resulted in altered enzyme activity over the substrates (orange) (e.g. Asn, Gln and AHA). Amino acids involved in catalytic activity are colored in red (Thr¹², Tyr²⁵, Thr⁸⁹, Asp⁹⁰ or Lys¹⁶²). (C and D) EcA monomer representations showing the amino acids in monomers interfaces. Molecular graphics were generated by PDB coordinates 3ECA (*E. coli*) (<http://www.rcsb.org>).

by Ala or Thr, located in the lid loop containing Tyr²⁵, increased enzyme stability, rendering higher resistance to AEP and increasing enzyme activity (Offman et al., 2011).

Regarding antigenicity, hydrophilic protein regions associated with long side chain-amino acids are closely related to antigenic sites. Studies involving EcA antigenicity showed that several amino acids fit into the characteristics described above (Tyr¹⁷⁶, Arg¹⁹⁵, Lys¹⁹⁶, His¹⁹⁷ and Lys²⁸⁸) (Figure 4A–D) (Jianhua et al., 2006; Mehta et al., 2014). Additionally, approaches using two distinct techniques to identify immunogenic peptides report an EcA fragment containing several bulky amino acids as the most immunogenic one (Werner et al., 2005). Interestingly, analysis of EcA tetramer structure reveals that some amino acids involved in the antigenicity are buried in the enzyme structure (Figure 4E and F). It is likely that, at very low concentrations such as those used in therapy, in addition to the tetrameric form, there are significant amounts of dimers with additional accessible residues, as previously demonstrated *in vitro* (Werner et al., 2005).

Recently, Mehta et al. (2014) demonstrated that EcA double substitution of Lys²⁸⁸Ser/Tyr¹⁷⁶Phe decreases significantly the enzyme immunogenicity, since the patient antibodies binding was reduced to less than 40%. As expected, Lys²⁸⁸ is located at the tetramer surface

(Figure 4E and F), but curiously Tyr⁷⁶ (Figure 4A and B) is buried between the dimers of the tetramer. Again, the tetramer dissociation may be related with this phenomenon.

As described previously, several ASNase undesirable characteristics have been ascribed to its GLNase activity (Aghaiypour et al., 2001; Chan et al., 2014; Derst et al., 2000; Mehta et al., 2014). In Era, substitution of Glu⁶³ and Ser²⁵⁴ led to a decrease in GLNase activity (Derst et al., 2000). In EcA, substitution of Asp²⁴⁸ by Ala revealed an effective decrease in Gln hydrolysis (Derst et al., 2000). However, the mutant also showed a significant decrease in Asn hydrolysis (about ~12% of the wild type).

Another study using molecular dynamics simulations combined with structural analysis and site directed mutagenesis, demonstrated that the double substitution Asn²⁴Ala and Tyr²⁵⁰Leu resulted in negligible GLNase activity and ~30% decrease of ASNase activity (Offman et al., 2011). As mentioned before, Asn²⁴ is located close to Tyr²⁵ from the lid loop (Figure 5A) and its substitution by Ala or Thr is related with proteolytic resistance to AEP. The GLNase activity decrease was associated with the active site cavity volume (Asn²⁴Ala, substitution) and tetramer compactness (Tyr²⁵⁰Leu, substitution) (Offman et al., 2011). It is noteworthy that the cytotoxicity of mutant EcA was significantly

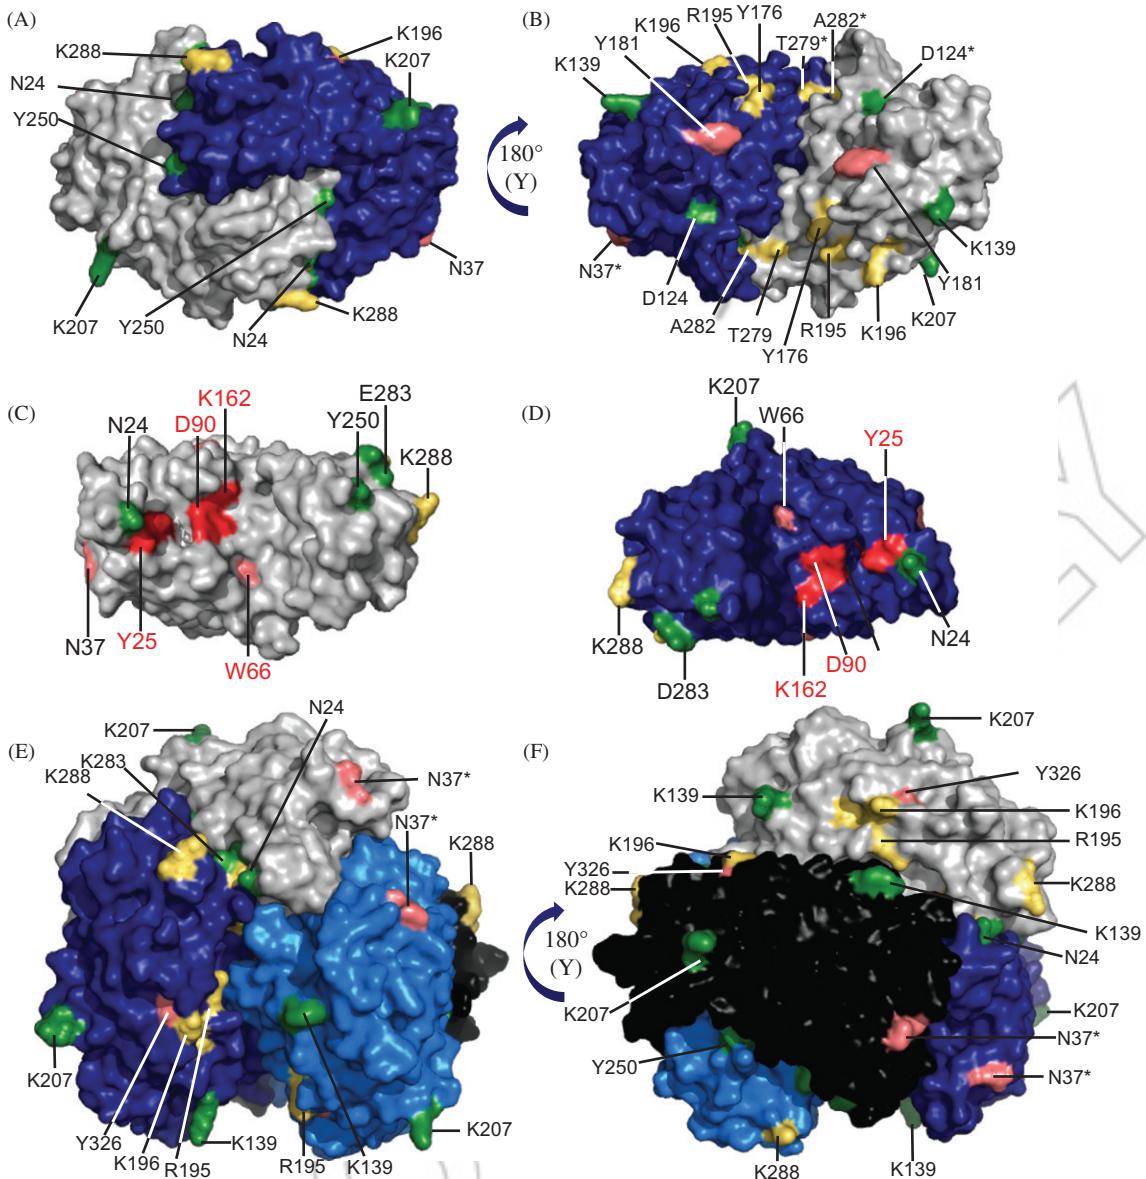

Figure 4. EcA structural surfaces representations of mutational approaches influencing enzyme stability and antigenicity. (A and B) EcA intimate dimer showing the surface mapping of amino acids whose replacement increases or decreases thermal (green) or proteolytic (salmon) enzyme stability or antigenicity reduction (yellow). (*) Amino acids substitutions performed in other bacterial species. (C and D) EcA monomer representations showing amino acids in monomers interfaces. (E and F) Tetramer interface with one dimer colored in gray and dark blue and the other in black and light blue. Molecular graphics were generated by PDB coordinates 3ECA (*E. coli*).

lower than that of the wild type enzyme. The authors argued that EcA dual activity is also associated with therapeutic toxicity, since mutants with lower GLNase activity also exhibited lower cytotoxicity (Offman et al., 2011).

Chan et al. (2014) also investigated additional factors of cytotoxicity of EcA mutants deficient in GLNase activity. Molecular dynamics simulation approaches combined with saturation site directed mutagenesis allowed the authors to identify an EcA glutamine residue (Gln⁵⁹) in the active site pocket able to perform saline interactions with the ligand (Figure 5B). It was demonstrated that the mutant enzyme carrying Gln⁵⁹ substitution by a Leu (EcA^{Q59L}) retains ~60% of ASNase activity, but no detectable GLNase activity.

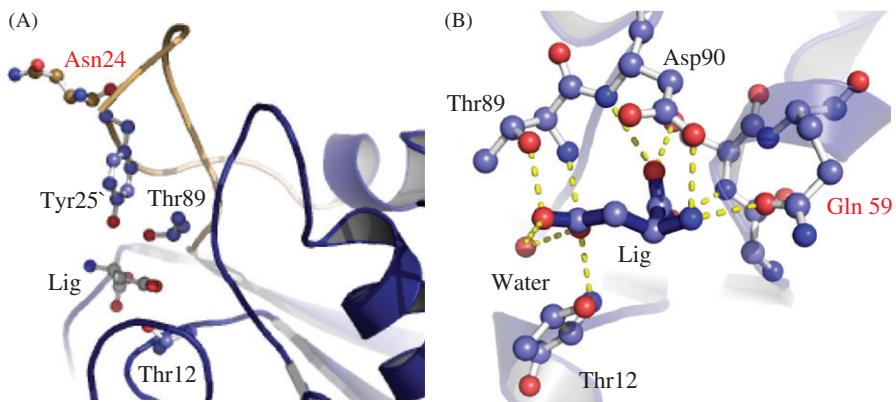

The mutant EcA^{Q59L} was able to kill efficiently cell lines with low ASNS levels, but did not display cytotoxicity against cell lines with high expression of this enzyme (Chan et al.,

2014). ASNS is able to catalyze the conversion of aspartate and glutamine to asparagine and glutamate through an ATP-dependent reaction, thus supplying ALL cells with Asn. Some studies report that ASNase-resistant forms of the disease may be associated with ASNS up-regulation in some patients (Richards & Kilberg, 2006). Nevertheless, the demonstration that EcA variants without GLNase activity are able to kill cancer cells with low ASNS levels is very important and may represent a promising therapy with less side effects for patients affected by tumors with this characteristic (Chan et al., 2014).

Recently, Verma et al. (2014) demonstrated that substitution of EcA Tyr¹⁷⁶Phe and Trp⁶⁶Tyr residues promotes a substantial decrease of GLNase activity, but ASNase activity is almost the same as that of the wild type enzyme. Tyr¹⁷⁶ and Trp⁶⁶ are very far from the enzyme active sites, at both dimers, and the effects of their replacements were related to

Figure 5. Amino acids involved in EcA enzyme stability and activity. (A) Representation of active site region of *E. coli* ASNase showing the position of residues (Thr¹², Asn²⁴, Tyr²⁵, Thr⁸⁹) and the ligand (aspartate). The loop containing Asn²⁴ and Tyr²⁵ are colored in light brown. Active site amino acids and aspartate are represented by CPK (O, red; N, blue; C, blue). Asn carbons are colored in light brown and the other amino acids in light blue. (B) Molecular binding aspartate in EcA. Red characters indicate Gln⁵⁹, whose replacement results in residual GLNase activity. The *E. coli* enzyme (PDB code 1NNS) is colored in blue and represented in cartoon. Amino acids are represented in ball and stick and colored by CPK (O = red and C = blue). Graphic models were generated by PyMOL (<http://www.pymol.org>).

an intricate network of indirect molecular interactions, which affects the enzyme quaternary folding with consequences in its activity (Figure 4). In subsequent studies, it was demonstrated that, contrary to the wild type enzyme, the mutant enzymes EcA^{W66Y}, EcA^{Y176F} and EcA^{K288S/Y176F} are able to down-regulate ASNS expression, however the reasons for this phenomenon are not yet understood (Mehta et al., 2014).

The studies presented in this section provide amazing examples of how EcA rational protein engineering can assist in a better understanding of catalytic mechanisms, substrate binding, enzyme folding and their relationship with cytotoxicity and immunogenicity. Engineered enzymes or new variants derived from studies presented here may have high potential for future alternative therapeutic treatments using recombinant ASNases. Additional studies involving structure determination and analysis of mutant enzymes with improved properties should provide a better understanding of EcA functional and structural features and open perspectives of creating new enzymes with personalized characteristics for different groups of patients. In addition to the rational modification based on structure analysis, emerging approaches based on computational analyses involving molecular dynamics, docking of substrates, among others *in silico* techniques, have proven to be very promising to guide rational enzyme modifications.

Concluding remarks and future perspectives

In general, ASNase is mainly produced by bacterial fermentation, and the native and pegylated forms of ASNase continue to be the most used in ALL therapy. Despite the benefits of conjugating ASNase with PEG, parallel negative side effects could be solved, in our opinion, through a better characterization of pharmacodynamics and pharmacokinetics, which would increase drug efficiency.

Nonetheless, due to ASNase importance in the treatment of several types of cancers, in particular leukemia, it is essential to search for new sources of this enzyme in order to increase its availability as a drug and reduce side effects. Considering the advantages of the use of microorganisms in bioprocesses and that very little is known regarding the magnitude of

microbial diversity, they may be considered a target source of genomic innovation in the search for new ASNases with improved properties compared with those currently employed in therapy. In this sense, more effort should be devoted, in our opinion, to the screening of new ASNase-producing microorganisms.

Rational protein engineering based on protein structure is another promising strategy to produce ASNases with improved pharmacodynamics, pharmacokinetics and toxicological profiles. Indeed, approaches involving site directed mutagenesis of residues in the active site were able to produce recombinant enzymes with good ASNase activity, but negligible GLNase activity. Additional procedures involving the introduction of structural disulfides and deletion of proteases cleavage sites may allow the production of more robust enzymes. There is little information on *Saccharomyces cerevisiae* ASNase and, giving the ease of cultivation and possibility of genetic manipulation of this yeast, we believe that such an enzyme deserves to be better investigated as an alternative to the existing bacterial ASNases. In particular, special attention should be paid to its better structural and kinetic characterization as well as to the rational engineering of the yeast enzymes by means of site-directed and random mutations.

One interesting technological approach that may contribute to improve ASNase production by recombinant microorganisms is the metabolic flux analysis (MFA), a powerful tool to estimate the metabolic state constrained by exchange of nutrient fluxes between cells and environment (Antoniewicz, 2013). This analysis has been successfully used to identify key nodes in the primary metabolism, which are characterized by significant changes to the partitioning of the flux under different conditions, and thus it can be considered as a potential control point manipulation (Boghigian et al., 2010; Goudar et al., 2014). Additionally, *Pichia pastoris*, which has been developed as an excellent host for heterologous genes using alcohol oxidase as a promoter, has potential for high cell density cultivations with high levels of protein expression and efficient secretion (Cregg et al., 2000). Therefore, MFA applied to ASNase production by recombinant *P. pastoris* seems to us an interesting alternative to be investigated, with determination of optimal culture conditions in terms of

temperature, methanol concentration and pH. This may be achieved through modeling of metabolic fluxes related to methanol-metabolizing pathway, which is important in the induction of the heterologous protein as well as yeast growth (Anasontzis et al., 2014).

The information gathered here also demonstrates a gap on novel alternatives and optimized protocols for ASNase bioproduction and purification. Therefore, research efforts should be addressed to these topics, with special focus on cultivation parameters and novel and cheaper purification strategies such as liquid–liquid extraction with ionic liquids. We hope that, in a near future, novel alternatives to bacterial ASNases can be available for ALL treatment, with better therapeutic results and less side effects.

Declaration of interest

The authors report no conflict of interest. This work was supported by grants from Brazil, specifically those financed by CAPES (reference numbers: #2805/2010 and #2609/2013), CNPq (reference number: #552652/2011-3) and FAPESP (reference numbers: #2013/08617-7 and #2013/19486-0).

Abbreviations used: Grx, glutaredoxin; Rho, rhodanese; ORFs, open reading frames; ROS, reactive oxygen species; Grx, glutaredoxin; Trx, thioredoxin; TrxR, thioredoxin reductase; GR, glutathione reductase; GSH, glutathione; *t*-BOOH, *t*-butyl hydroperoxide; DTNB, 5,5'-dithio-bis (2-nitrobenzoic acid); NEM, N-ethylmaleimide; IPTG, isopropyl-1-thio-β-D-galactopyranoside; DTT, 1,4-dithiothreitol; DTPA, diethylenetriaminepentaacetic acid; HPLC, high performance liquid chromatography.

Keywords: Glutaredoxin (Grx), Reactive Oxygen Species (ROS), Glurho, Rhodanese (Rho), *Xylella fastidiosa*.

Abstract: The *Xylella fastidiosa* is a phytopathogen and the causal agent of diseases in several commercial plants, accounting for high financial losses. The genome analysis of *X. fastidiosa* ORFs revealed a new putative gene, present in all strains sequenced to date, whose product may possesses three domains: the N-terminal domain has a high similarity with the monothiol glutaredoxins (Grx), which are related to several redox processes. The C-terminal portion presents similarity to Rhodanases (Rho), involved in the sulfur (S) metabolism and the central region presents similarity to Fe-S cluster superfamily. Due to these characteristics this ORF was nominated *glurho*. The ORF translation revealed N-terminal and the C-terminal domains also contain two cysteines residues (Cys³³ and Cys²⁶⁶), which are essential to Grx and Rho activity in enzymes described to date, indicating that both domains may be functional. Additionally, proteomic studies revealed that the Glurho protein is highly expressed in *X. fastidiosa* inside the cell and in its biofilm. Since that reactive oxygen species and cyanide production by the host are very common processes in defense against pathogen infection and predation, this protein may play a key role in bacterial protection and resistance against the host defenses. In this work, we performed databases searches, which revealed that Glurho homologues are only present in prokaryotes, most of which are pathogenic to plants and animals, due to these characteristics, Glurho protein may represent promising targets for therapeutical drugs. Corroborating with this view, individual sequence alignment with well characterized glutaredoxins, Fe-S cluster containing proteins and rhodanases, revealed that the domains share low identity with their counterparts, but the Grx and rhodanese domain posses very conserved domains related to the biochemical activity of the proteins. In order to characterize the biochemical properties of Glurho, the recombinant enzyme was expressed as His-tagged protein and purified by immobilized metal affinity chromatography (IMAC) to homogeneity. To evaluate the activity, supposedly conferred by Grx domain, the disulfide reduction and peroxidase activity glutathione dependent assays were performed but none activity was detected. However, enzymatic evaluation of the rhodanese function revealed that Glurho protein is able to detoxify efficiently cyanide to thiocianate *in vitro* with higher efficiency (5 ×) than bovine rhodanese. We also demonstrated that the cysteines residues are essential to rhodanese activity, since the NEM alkylation annihilated enzyme activity. Finally, the substitution of the cysteine residue from rhodanese domain (Cys²⁶⁶) by a serine abolished the rhodanese activity, indicating that the residue is essential to the enzyme functionality. Meanwhile the Cys³³ replacement by serine increased the rates of the rhodanese activity in 3-fold. We also investigate the *in vivo* effects of KCN tolerance by the heterologous enzyme expression in *E. coli* BL21 (DE3) cells, which revealed that Glurho is able to protect the bacterial cells against high concentrations of cyanide. However, contrastingly with the *in vitro* rhodanase mutants biochemical data, the *E. coli* BL21 (DE3) cells expressing Glurho^{C33S} and Glurho^{C266S}, indicating that *in vivo* cyanide resistance phenotype is dependent of Cys³³ integrity.

Introduction

Xylella fastidiosa is a gram-negative bacterium which infect the plant xylem of many taxonomic groups of economic importance such as citrus, alfalfa, coffee, grape, almond, peach and pear [1–4]. The bacterium is transmitted by contaminated plants through cicada, a specific vector which the mechanism of interaction with the host is until now poorly unknown [2,5,6].

The *X. fastidiosa* genomes contains several genes related to virulence, adhesion and response to plant defenses, among them, several genes related to the ROS metabolism represented by antioxidant enzymes [7–10]. Smolka *et al.* [11], using two-dimensional gel electrophoresis allied to mass spectrometry, demonstrated that a substantial amount of antioxidant proteins are expressed in high concentrations in the strain of the *X. fastidiosa* 9a5c. Among them, the ORF XF2394, a hypothetical protein, was detected in large amounts in both, intracellular and extracellular contents. The sequence analysis of the ORF XF2394 using CDD program (<http://www.ncbi.nlm.nih.gov/Structure/cdd/cdd.shtml>), revealed that it possesses three domains: the N-terminal domain has a high similarity to the monothiol glutaredoxins, which are related to several redox processes; the C-terminal portion presents similarity to Rhodaneses, involved in the sulfur (S) and cyanide (CN⁻) metabolism; and the central region is similar to Fe-S cluster biosynthesis superfamily, related to sulfur assimilation and oxidative stress defense. Due to these features, in this study we have named *Glurho* (for Glutarhodanese) the product of the ORF.

Glutaredoxins (Grx) are low molecular weight oxidoreductases (~12KDa) that have at least a cysteine residue in its active site used in oxireduction processes [12,13]. Grx proteins can be classified according to the number of cysteine residues as dithiolic (Cys-X-X-Cys motif) or monothiolic (Cys-X-X-Ser) [12,14–17]. Using the reactive cysteines, dithiol Grxs perform thiol-disulfide exchanges reducing their disulfide containing substrates. The reduction mechanism requires glutathione (GSH), glutathione reductase (GR) and NADPH reducing equivalents [18,19]. Additionally, to the disulfide reduction, it has been demonstrated that some yeast Grx are able to act as glutathione peroxidases, revealing an additional protective role of these enzymes to the organisms [20,21].

The *X. fastidiosa* Glurho protein presents resemble monothiol glutaredoxins which is characteristic of [19] which is highly conserved from bacteria to humans [16,22]. Therefore it

is possible that the monothiol glutaredoxin domain of Glurho could exhibit the same mechanism of action of dithiol glutaredoxins since the reduction mechanism of Grxs may be monothiolic even to some dithiolic Grx [19,23].

Relative to the central domain in Glurho the iron-sulfur assembly proteins, a variety of proteins widely distributed in nature, from bacteria to mammals, are able to syntetathize the Fe-S cluster [74,75]. They serve a variety of biological roles, including electron transport, catalytic, structural, and sensory roles [76]. The free iron can generate oxygen radicals via Fenton-like reactions that may result in damage macromolecules [74,75,76]. The connection between Fe metabolism and oxidative stress during infection of pathogens has been demonstrated, since some microorganisms require the enzymes necessary for the synthesis of Fe-S to respond to oxidative stress or in the case of phytopathogen *Erwinia chrysanthemi* maintain a strong virulence. As the Grx proteins the Fe-S activity is also centered in conserved cysteine residues [74,75,76].

It is well known that the synthesis of CN⁻, together with ROS production represent defense strategies widely used by plants against pathogens and predators [24–26]. Among the enzymes involved in detoxification of CN⁻, the rhodanese (Rho) are one of the most extensively studied since they are widely distributed in nature [27–29]. The enzyme is able to catalyze the reaction between thiosulfate and cyanide leading to the formation of sulfite and the less toxic thiocyanate [28]. In bacteria, such as *Escherichia coli*, the most studied representative rhodanese protein is GlpE, which has been proposed to possess great importance on organism homeostasis since plays essential biochemical roles acting as thiosulfate-cyanide sulfurtransferase [30].

The Glurho rhodanese-like domain contains a cysteine residue at C-terminal portion on the position 266, which might be involved in cyanide (CN⁻) detoxification and/or sulfur metabolism [27,28,31,32]. Although almost all rhodanese researches focus on cyanide resistance, the occurrence of so many rhodanases-like proteins suggests alternative functions, including sulfur and selenium metabolism and biosynthesis of prosthetic groups in iron-sulfur proteins [28,31–33].

Cipollone, *et al.* 2007 [28] divided the rhodanese superfamily into 4 groups according to some common characteristics. Although the amino acids can differ significantly at the sequence level, the three-dimensional structure has common characteristics even among different organisms [28]. The Group 3 is represented by enzymes containing the catalytic

rhodanese domain combined with other globular protein domain. In this case the involvement of a rhodanese domain in a given process seems to be related to the functional properties of the accompanying domain [36–38].

Protein domains represent the basic evolutionary units that form proteins. The duplication and exchange by recombination and fusion, followed by divergence are the most frequently mechanisms for protein evolution [39]. Thus, the recombination of existing domains may be a major mechanism that modifies protein function and increases proteome complexity. The fusion of the proteins related to consecutive metabolic steps seems to be of great importance for some pathogens. An important example is the Trx System, which is constituted by two enzymes: the thioredoxin (Trx) and thioredoxin reductase (TrxR), a ubiquitously system spread among all organisms [40–43] responsible for the reduction of the peroxiredoxins, which are very important enzymes to the cell redox homeostasis [44–46].

Curiously, in some pathogens the two enzymes of Trx system are fused. In *Mycobacterium leprae* thioredoxin reductase is a natural hybrid that contains a Trx molecule attached to the C-terminal portion [47]. The alkyl hydroperoxide reductase F (AhpF), found in several bacteria such as *Salmonella typhymurium*, is also a modified TrxR, which has an additional N-terminal domain (NTD), produced by the fusion of two thiorredoxin molecules [48]. AhpF belong to the AhpR complex that is formed by the AhpF and the peroxiredoxin AhpC. In fact AhpF is an enzyme specialized in AhpC reduction [49]. In both the cases, it has been shown that these fused enzymes are of great importance in resistance to pathogen infection and establishment in the host [50,51].

Thus, the *X. fastidiosa* Glurho appears to be a unique protein found only among prokaryotes which can be involved in the resistance of pathogens and vectors of plant defenses. Additionally, it can be related to the sulfur metabolism and training of clusters Fe-S [28,32,52].

Since reactive oxygen species and cyanide production by the host are very common processes in defense against pathogen infection and predation, this protein may play a key role in bacterial protection. In this work, we show that Glurho homologues are only present in prokaryotes, most of which are pathogenic to animals and plants, due to these characteristics, Glurho protein may represent promising targets for therapeutical drugs. Corroborating with this view, individual sequence alignment of Glurho domains with proteins Grx, Fe-S cluster assembling proteins and rhodaneses of several organisms, revealed that the domains share low

identity with their counterparts. In order to characterize the biochemical properties of Glurho, the recombinant enzyme was expressed as His-tagged protein and purified to homogeneity. To evaluate the activity, supposedly conferred by Grx domain, the disulfide glutathione dependent reduction and peroxidase activity assays were performed but none activity was detected. However, enzymatic evaluation of the rhodanese function revealed that Glurho protein is able to transfer efficiently sulfur to cyanide forming thiocianate *in vitro* with higher efficiency (5 ×) than the well known bovine rhodanese. We also demonstrated that the cysteines residues are essential to rhodanese activity, since the NEM alkylation annihilated enzyme activity. The substitution of the cysteine residue from rhodanese domain (Cys²⁶⁶) by a serine abolished the rhodanese activity, revealing that the Cys²⁶⁶ residue is essential to the enzyme functionality. Curiously, the Cys³³ replacement by serine increased the rhodanese activity in 3-fold, suggesting a regulatory role of the residue. We also investigate the *in vivo* effects of KCN tolerance by the heterologous enzyme expression in *E. coli* cells, which revealed that Glurho is able to protect the bacterial cells against cyanide compounds even at high concentrations (1.5 mM). However, contrastingly with the *in* data cells expressing Glurho^{C33S} and Glurho^{C266S} were very susceptible to KCN toxicity, indicating that *in vivo* cyanide resistance phenotype is dependent of Cys³³ integrity.

Materials and methods

Glurho ampification, cloning and sequence - The open reading frame (ORF) XF2394 (NCBI accession number: KIA57599.1) was amplified by PCR using with template genomic DNA from *X. fastidiosa* 9a5c strain. The oligonucleotides XF2394_F-5'-CGCGATCCATATG ATGCCGCAGTGCGGTTTCTGC-3'and XF2394_R-5'-CGCAAGCTTGGATCCAA TACTTCGGCACACTCGC-3' containing *Nde* I and *Bam* HI cloning adapters (underlined sequence) were designed based on gene sequence presents at *X. fastidiosa* database (<http://www.xylella.lncc.br/>). Amplified DNA fragments was digested with *Nde* I and *Bam* HI and cloned into *Nde*I-*Bam* HI-digested pET15b vector. An *E. coli* DH5 α strain was transformed with the construct and cells and cultured to increase plasmid production. The resulting pET15b/*Glurho* vector was sequenced in an ABI 3730 DNA Analyzer using the BigDyeTerminator v3.1 Cycle Sequencing Kit (Applied Biosystems). The plasmids containing the correct constructs were used to transform *E. coli* BL21 (DE3) strains.

Site Directed Mutagenesis. The pET15b/*Glurho* plasmids were used to generate the two individually Glurho mutant proteins carrying cysteines (Cys³³ and Cys²⁶⁶) substitutions to serines. The substitutions were performed using the Quick Change II kit (Stratagene) and the mutagenic primers Glurho^{C33S}_F (5' ATGCCGCAGTCCGGTTTCT 3'), Glurho^{C33S}_R (5' AGAAAAACCGGACTGCGGCAT 3'); Glurho^{C266S}_F (5' GCATTCTTGCTCATCAC GGC 3') and Glurho^{C266S}_R (5' GCCGTGATGAGACAAGAATGC 3'). The reaction products were used to transform *E. coli* XL1-Blue strain and single colonies were grown on liquid media during 16hs and then the plasmids were extracted, purified and sequenced to confirm the codons substitutions, and used to transform *E. coli* BL21 (DE3) strains.

Protein Expression and purification .Single colonies of *E. coli* BL21 (DE3) strains containing the pET15b/*glurho*, pET15b/*glurho*^{C33S} and pET15b/*glurho*^{C266S} plasmid were inoculated in LB medium (20 ml) containing 0.1 mg ampicillin/ml and grown overnight at 37 °C. Afterwards the cell cultures were transferred to 1 liter of fresh LB medium, and geowed until OD₆₀₀ reached 0.6–0.8. The expression of the recombinant proteins were induced by the addition of 0.3 mM IPTG, and the cells were maintained at 18 °C/16hs/250 rpm in a orbital shaker. After this period, cells were harvested by centrifugation, and the pellets were

resuspended in start buffer (50 mM sodium phosphate buffer, pH 7.4, containing 50 mM NaCl, 20 mM imidazole and 2 mM phenylmethyl sulfonyl fluoride (PMSF) and the cells were disrupted by sonication. The cell extracts were kept in ice during streptomycin sulfate 1% treatment for 20 min. The supernatants were clarified by centrifugation, homogenized by filtration and purified by nickel affinity chromatography using the HisTrap column (GE Healthcare) by imidazole gradient (50-500 mM). The Glurho^{WT}, Glurho^{C33S} and Glurho^{C266S} recombinant proteins were predominantly eluted at 500 mM imidazole fractions. Imidazole was removed using a PD10 desalting column (GE Healthcare) and purified proteins were kept in 50 mM sodium phosphate buffer (pH 7.4) containing 50 mM NaCl. The enzymes purity were confirmed by SDS-PAGE and the concentrations were determined by the molar extinction coefficient for reduced *X. fastidiosa* Glurho ($\epsilon_{280} = 25.565 \text{ M}^{-1} \text{ cm}^{-1}$) using the ProtParam tool ([http://www.expasy.ch/tools/ protparam.html](http://www.expasy.ch/tools/protparam.html))

Evaluation of the Glutaredoxin Disulfide Reduction Activity. The Grx activity conferred by Glurho was evaluated by the standard assay for Grxs which measures the ability of the protein to reduce the mixed disulfide formed between a GSH molecule and β -hydroxyethyl disulfide (HED) spectrophotometrically ($\lambda=340 \text{ nm}$) at 30 °C [53]. The reaction mixture containing 0.1 M Tris-HCl pH 7.4; 1 mM GSH; 6 $\mu\text{g}/\text{ml}$ GR and 0.7 mM HED was incubated at 30 °C for three minutes for the formation of the mixed HED disulfide and then 0.2 mM NADPH was added, the reaction was started by the addition of Glurho 1 μM and followed by the decrease in the absorbance at 340 nm due to the oxidation of NADPH during 250 seconds.

An additional disulfide reduction assay was performed using as substrate mixed disulfide already formed between Cys and GSH (Cys-S-SG). The reaction mixture containing GSH 1 mM, GR 6 $\mu\text{g}/\text{ml}$, Tris-HCl pH7.4 at 100 mM, NADPH 0.2 mM, Cys-SSG 100 μM and Glurho protein at 1 μM was measured spectrophotometrically ($\lambda=340 \text{ nm}$). The mix solution containing all the reagents except the NADPH and the Cys-SSG disulfide was incubated at 37 °C for 1 minute and then the NADPH was added, after the stabilization the Cys-SSG disulfide was added and the absorbance was recorded by 250 seconds to evaluate the NADPH oxidation.

Evaluation of Glurho GSH dependent Peroxidase Activity. The GSH dependent peroxidase activity of Glurho with *t*-BOOH was evaluated *in vitro* by NADPH oxidation assay. The

components of the reactions were 0.4 mM NADPH, 1 mM GSH, 6 µg/ml Glutathione reductase, 1µM Glurho and 1 mM *t*-BOOH. The reactions were performed in buffer Tris HCl, 1mM (pH 7.4) in a final volume of 1 ml. The reaction was started by the addition of Glurho and the absorbance at 340 nm was recorded for 200 seconds.

Evaluation of DTT dependent peroxidase activity. The rate of DTT oxidation catalyzed by Glurho in the presence of the H₂O₂ as substrate was evaluated by monitoring the change in absorbance at 310 nm for 250 seconds due to formation of the DTT disulfide [54]. The assay contained: 100 mM Tris-HCl pH7,4, H₂O₂ 1 mM, Glurho 1 µM, and 10 mM DTT in a 1 ml quartz cuvette at 37 °C.

Cyanide sulfurtransferase activity. To evaluate the rhodanese activity of Glurho, Glurho^{C266S} and Glurho^{C33S} proteins to convert CN⁻ to SCN⁻ was accomplished spectrophotometrically as described previously [55,56]. The reaction consisted of potassium phosphate (KH₂PO₄) 40 mM, KCN 50 mM, sodium thiosulfate (Na₂S₂O₃) 50 mM and Milli Q water in 1 ml of reaction. The reactions were initiated with the addition of 0-1.2 µM of Glurho, Glurho^{C33S} or Glurho^{C266S} and after 5 minutes the reactions were stopped by adding formaldehyde 2,5%, and then by adding ferric nitrate (100g of Fe(NO₃)₃.9H₂O and 200 ml of 65% HNO₃ per 1500 ml) in a final volume of 3ml. In the reaction the cyanide is converted to thiocyanate that in acidic conditions and in the presence of Fe⁺³ results in a red intermediated, which is quantified spectrophotometrically ($\lambda=460$ nm). As a positive control were used the same concentrations of bovine rhodanese and to the negative control no enzyme was added to reaction mixtures.

Glurho heterologous expression in KCN⁻ containing media. Cultures of *E. coli* BL21 (DE3) harboring the plasmid pET15b (empty vector) and pET15b/*Glurho*, pET15b /*Glurho*^{C266S} and pET15b /*Glurho*^{C33S} (recombinant vectors) were grown in LB medium containing 100µg ampicillin/ml overnight at 37 °C/ 250 rpm. After this period the cultures were transferred to 15 ml of fresh LB broth and the cell culture were grown until OD₆₀₀ reached 0.6–0.8. The cultures in exponential phase were diluted to OD₆₀₀ = 0.02 with or without IPTG 0.1 mM and were exposed to 0.3 mM, 1.3 mM, 1.5 mM and 2.5 mM of KCN⁻ during 24h, and the OD₆₀₀ of the cultures were recorded.

Evaluation of sulfur acceptors. To evaluate the Glurho sulfur transfer activity, NADPH oxidation assay was performed. The assays were performed in a final volume of 1 ml containing potassium phosphate buffer, 50 mM (pH=7.4); *E. coli* TrxR, 0.2 μ M; NADPH, 150 μ M; *X. fastidiosa* Tsnc or *E. coli* Trx, 10 μ M. The reactions were initiated by the addition of sodium thiosulfate, 80 mM and Glurho, 10 μ M, and the absorbance was monitored spectrophotometrically (λ =340 nm) by 150 seconds.

Assessment of secondary structure by circular dichroism spectroscopy. Secondary structural elements of Glurho and mutants were determined experimentally by circular dichroism (CD) using a Jasco J-720 spectropolarimeter (Jasco, Easton, MD). Purified recombinant wild type and mutant enzymes (10 μ M) in 10 mM NaH₂PO₄ buffer (pH 7.5) were used for the Far-UV CD analysis from 195 to 260 nm at 20°C in a 0.1-cm-gap cuvette. The molar ellipticity values (θ) were calculated using a molar concentration of and the number of 328 amino acids. The Glurho and mutants secondary structures content were determinate using the K2D software (42).

Results and discussion

X. fastidiosa Glurho homologues are restricted to prokaryotes

The homology analysis of Glurho protein with translated genebank sequences using the program BlastX (<http://blast.ncbi.nlm.nih.gov/Blast.cgi>) revealed that this protein is present only in a small group of organisms (21), excluding the *X. fastidiosa* strains, all of them are prokaryotes (**Fig. 1**). Our results also shows that the vast majority of organisms that possess the *glurho* gene belongs to the genus *Xanthomonas* and are causative agents of several diseases in plants. Additionally, some human pathogens of the *Stenotrophomonas* genus, the causative agent of respiratory diseases, also possesses homologues to Glurho. The remaining species are found from environmental genomic projects and biological data are unavailable.

Sequence alignment and conserved domain analysis

As mentioned before, the analysis of Glurho using the conserved domain database, (www.ncbi.nlm.nih.gov/Structure/cdd/cdd.shtml) [57] revealed that Glurho protein is formed by three distinct domains comprising a Grx like (N-terminal), Fe-S cluster assembly (central) and a rhodanese like domains (C-terminal). To investigate the conservation of these putative domains we performed alignments of the Glurho protein with well-characterized counterparts of other organisms. The alignment of the Grx like domain revealed that the Grx domain is very conserved among eukaryotes and prokaryotes, including the catalytic cysteine which is embedded in the CGFS motif (**Fig. 2A**, red asterisk), characteristic of monothiolic glutaredoxins [19,58]. The Fe-S cluster assembly like domain, is not very conserved among the organisms and the alignment was performed using only bacterial counterparts. An important observation is the fact that Fe-S cluster assembly like domain of Glurho do not posses multiple cysteine residues as the other proteins analyzed (**Figure 2B**, green asterisk). As an example, the *Escherichia coli* ISCa (Iron-Sulfur Cluster Assembly protein) presents three cysteine residues that are essential to the assembly of Iron-Sulfur cluster, since their substitutions to serines abolishes the protein activity [59–61]. Therefore, despite the similarity presented with Fe-S cluster assembly detected by the CCD database, this domain does not appear to be functional. Finally, the analysis of the primary sequence of the rhodanese-like domain, shows that the similarities with other rhodanases are very low. However, the

conserved cysteine residue essential to enzyme activity is present at Glurho domain (Cys^{266}) (**Fig. 2C**, blue asterisk). Since that the *in silico* analysis suggests that at least two domains may be functional, we decided to express and purify the recombinant Glurho protein to assess its biochemical properties.

Glurho is not effective in disulfide reduction or hydroperoxide decomposition.

Initially, we tested the oxidoreductase activity of the Glurho Grx domain, using the standard assay of the mixed disulfide disulfide reduction formed between β -hydroxyethyl disulfide (HED) and glutathione (β -ME-SG) [23,62]. Our results demonstrate that no significative differences were observed between the negative control (without protein) and the reaction containing Glurho, indicating that Glurho is not able to reduce the β -ME-SG disulfide (**Figure S1A**). Since that β -ME-SG disulfide uses a synthetic compound (HED), we also tested the Glurho oxidoreductase activity using as substrate a mixed disulfide between cysteine and glutathione (Cys-S-SG), which may resemble more substantially the endogenous substrate of the Grx, however, no activity was detected (**Figure S1B**). Despite that Gluro Grx domain not having shown activity as a disulfide reductase, is well known that some monothiolic Grx presents low or null affinity in reducing mixed glutathione disulfides, which seems to be related to slight structural differences at their active sites environment [19]. Additionally, recent studies performed by Li and colleagues 2010, [63] using structural comparisons and sequence alignments of monothiol and dithiol Grx, showed that all monothiol Grx (such as those with the catalytic motif CGFS), posses an insertion of 5 amino acids, not conserved in sequence, in close vicinity in the sequence to the catalytic cysteine. In fact all monothiolic Grx that have these five additional amino acids, coincidentally do not possess activity in the HED assay [63]. On the other hand, dithiol Grx as well some monothiol ones, as the yeast ScGrx6, ScGrx7 and poplar GrxS12, whose lacks the 5 additional amino acids exhibit activity in the HED assay. The analysis of the protein sequence of the Glurho Grx like domain makes clear the existence of the additional amino acids close to the CGFS motif (**Figure 2A**), indicating that the absence of disulfide reductase activity may rely in this structural feature.

It was previously demonstrated that the yeast glutaredoxins Grx1 and Grx2 can directly reduce hydroperoxides acting as glutathione peroxidases [21]. Furthermore *grx1* and *grx2* yeast mutants are sensitive to oxidative stress induced by hydroperoxides [21]. Therefore

peroxidase activity assays were carried out to verify the possibility of the Grx domain of Glurho to act as GSH dependent peroxidase. To test the peroxidase activity over organic peroxide (tert-butyl hydroperoxide) we employed the NADPH oxidation assay using glutathione reductase (GR) and GSH. The results demonstrated that Glurho was not able to decompose the *t*-BOOH (**Figure S1C**). We also tested the peroxidase activity using the dithiolic reductant DTT, by the oxidation of DTT assay using hydrogen peroxide as substrate. However no enzymatic activity over hydroperoxide decomposition was detected (**Figure S1D**). Together our results demonstrated that Glurho is not effective as a peroxidase.

Glurho is able to convert cyanide to promote cyanide detoxification

Rhodanases are a group of enzymes that uses a cysteine residue to catalyze the reaction between thiosulfate and cyanide leading to the formation of sulfite and thiocyanate [27,28,30]. To evaluate the rhodanese activity of Glurho we employed the method described by Westley (1981) in which the thiocyanate formation in acidic conditions and in the presence of Fe⁺³ results in a red colored intermediate that can be quantified spectrophotometrically. The reactions were carried out using growing Glurho concentrations and our results demonstrated that the thiocyanate formation increases proportionally with Glurho concentration (**Fig. 3A**).

Since that the Glurho presented rhodanese activity, we also decided to compare the Glurho rhodanese activity with one of the most well studied enzymes of this class: the bovine liver rhodanese (Rhobov) [56,64]. For this purpose, equivalent concentrations of the enzymes (1 μM) were used in the thiocyanate formation assay and reactions were stopped after five minutes. Our results demonstrated that the *X. fastidiosa* Glurho exhibited a specific activity five folds higher than the Rhobov (**Fig. 3B**). These results are very interesting since that cyanide production in response to grazing and predation by a variety of plants are well known [70,71], and Glurho may act as an defense front to enable the insect resistance to plant defenses. In fact some species that are infected by *X. fastidiosa* like almond, alfalfa and peach trees are able to produce cyanogenic compounds in their stem (e.g. prussic acid) [72]

Evaluation of additional sulfur acceptors

It has been demonstrated that the additionally to the cyanide, the rhodanases are able to exerts the sulfurtransferase activity over another substrates [32,36,37,38]. Recent studies

demonstrated that the thioredoxin (Trx) is an efficient rhodanese sulfur acceptor [65]. In this case, the sulfur atom form a mixed disulfide with Trx cysteine which is reduced by the thioredoxin reductase enzyme (TrxR) using reducing equivalents from NADPH, producing hydrogen sulfide (H_2S) (**Figure S2A**). To evaluated if Glurho is able to act as sulfurtransferase to the Trx, we performed a NADPH oxidation assay, using *E. coli* Trx and *E. coli* TrxR or Tsnc, a Trx from *X. fastidiosa*. The results demonstrated that EcTrx and Tsnc were not able to accept sulfur atoms from Glurho (**Figure S2B**).

Although the results have shown that Glurho is not capable to transferring sulfur atoms to *E. coli* Trx, the results are inconclusive to Tsnc. Since that the *E. coli* TrxR was used in the NADPH oxidation assay, the sulfur transfer by Glurho to the Tsnc could have occurred but was not detected due to a inefficiency of the *E. coli* TrxR to reduce *X. fastidiosa* Tsnc, because the proteins are from different species, a phenomena related before [73].

In reason of observations presented above, additional cyanide sulfurtransferase assays were performed using higher Tsnc concentrations (1 or 2 molar equivalents). In addition to Tsnc, the low molecular weight thiolic compounds DTT and GSH were also tested as sulfur acceptors. The sulfur transfer to the potential acceptors catalyzed from Glurho would lead to a decrease of thiocyanate formation due to the competition with KCN^- for sulfur atoms. The results revealed the reduction of thiocyanate formation when DTT (**Figure S3C**) and GSH (**Figure S3B**) are added to the reactions, while no differences were observed when Tsnc is added (**Figure S3A**), indicating that Tsnc is not able to accept sulfur atoms from Glurho. On the other hand, the Glurho was able to exert the sulfurtransferase activity over thiolic compounds, which may indicate that the CN^- may not be the sole substrate for the enzyme.

Cysteines integrity is essential for Glurho sulfurtransferase activity

As mentioned before, all the rhodanases described to date uses a cysteine residue to capture a sulfur atom and transfer to their substrates [27,28,30,56,64]. To confirm that the Glurho activity is centered on a cysteine residue, previously to ferrithiocianate assay, the enzyme cysteines were alkylated using N-ethylmaleimide (NEM). Our results revealed that the cysteine alkylation abolished entirely the rhodanese activity (**Fig. 4A**), confirming that the cysteines integrity is essential to the enzymatic properties of Glurho.

Since that the Cys^{266} residue is inserted in rhodanese domain is reasonable to think that it is responsible for the sulfutransferase activity of Glurho (**Fig. 2C**). Moreover, since there is

no activity was detected for the oxidoreductase domain Grx, it is possible that the residue Cys³³ may play a structural role in the enzyme. Thus their replacement could affect the enzyme structure reducing or even eliminating their activity. In order to unequivocally identify the Cys²⁶⁶ as the residue as responsible for rhodanese activity and assess whether Cys³³ exerts a structural role on Glurho, we have performed site directed mutagenesis replacing individually the cysteines residues by serines.

Therefore the sulfurtransferase activity assay was performed to evaluate the enzyme activity of the mutants Glurho^{C33S} and Glurho^{C266S} compared to the wild type protein. As expected, the rhodanese activity of Glurho^{C266S} was virtually abolished (**Fig. 4B**). On the other hand the Glurho^{C33S} presented an unexpected increase of the rhodanese specific activity 3-fold higher than the wild type enzyme (**Fig. 4B**).

The higher rhodanese activity of the Glurho^{C33S} mutant, indicates that despite the Cys³³ of the Grx domain do not play roles in oxidoreductase processes or over the enzyme structure, it may play a regulatory role in enzyme rhodanese activity. An example is ThiI, a bifunctional enzyme required for the biosynthetic pathway of 4-thiouridine, a modified base present in certain bacterial tRNAs and Thiazole moiety of Thiamine [24]. Most of the protein related to ThiI family presents an N-terminal THUMP domain involved in a variety of RNA modifications and a C-terminal rhodanese domain. In the reaction mechanism proposed for ThiI, desulfurase (IscS) first catalyses the transfer of sulfur from a free Cys to the Cys catalytic residue of the rhodanese of ThiI (Cys⁴⁵⁶), and then residue Cys³⁴⁴ acts as a nucleophile forming a Cys⁴⁵⁶-Cys³⁴⁴ disulfide releasing 4-thiouridine [36,37,38].

Since the enzyme ThiI also represents a rhodanese fusion protein with two domains containing cysteines, which have as intermediate a disulfide between the cysteines of both domains. Therefore, the Glurho Cys³³ could form a disulfide as an intermediate in the cycle of sulfur transfer to the CN⁻, and thus modulate the activity of the enzyme. In this context, the disulfide would need to be reduced to the enzyme could perform another round of sulfur transfer. To test this hypothesis assays were conducted, fixing Glurho concentration varying the time of the experiment without the addition of a reductant. As can be seen in Figure 5, even without the presence of a reducing agent the amount of formed thiocyanide increased with time, indicating that no disulfides are formed between Cys³³ and Cys²⁶⁶.

Heterologous expression of Glurho confers high cyanide resistance to E. coli cells

It has been reported 1 mM of cyanide causes significant inhibition of aerobically growing of *E. coli*. Therefore, to verify any protective effect of Glurho against cyanide toxicity, exponential phase cultures of *E. coli* BL21 (DE3) containing the empty vector (pET15b) or carrying the plasmid with *glurho* gene (pET15b/Glurho) were adjusted to OD₆₀₀ = 0.01 and challenged with 1.5 mM of KCN in the presence of IPTG (0.1mM). Since that the basal expression levels of heterologous proteins are significantly high in *E. coli* BL21 (DE3) cells, we also performed the same experiment without the IPTG addition [77]. After 24 hours of growing of the cells cultures the optical density of the cells cultures were measured. The results demonstrated that optical density of the cultures cells carrying the recombinant vector but uninduced with IPTG, presented growing rates 83% higher than the cells carrying the empty vector. To IPTG induced cells the rates where 91% higher than the cells carrying the empty vector, indicating that cyanide resistance are dependent of recombinant protein inside the cell (**Fig. 11A**).

The ability to cyanide detoxification *in vivo* of Glurho^{C33S} and Glurho^{C266S} were also tested using the same conditions described before to non-IPTG induced cells. Curiously, the *E. coli* cells strains carrying the recombinant vectors with cysteine substitutions (pET15b/*Glurho*^{C33S} and pET15b/*Glurho*^{C266S}) were not able to confer any resistance to the cells under inhibitory cyanogenic conditions (**Fig.11B**). Indicating that the Cys³³ may play an important role in cyanide resistance *in vivo*.

Concluding Remarks

In this work, we performed the first characterization of the Glurho a multi domain enzyme, presenting homologues only in prokaryotes, most of which are pathogenic to animals and plants. Despite that no classical oxidoreductase or structural role was detected to Grx domain, the evaluation of the rhodanese function revealed that Glurho is able to detoxify efficiently cyanide to thiocianate *in vitro* with higher efficiency (5 ×) than bovine rhodanese. Since *X. fastidiosa* is a 2-host pathogen the high resistance to cyanide may be very important to the insect vector, since some *X. fastidiosa* target plants produces cyanogenic compounds as a way to protect themselves from insect predation. Additional importance to the Glurho sulfurtransferase activity may be related to the large amounts of sulfur on *X. fastidiosa*'s biofilm [35] and the presence of Glurho on extracellular environment [11], which may

indicate an important role on bacterial adhesion and maintenance on xylem vessel. Curiously, the *glurho* gene position on *X. fastidiosa* genome are very close to several genes related to biofilm extracellular polysaccharides (EPS) biosynthesis such as Xanthan gum [66, 67].

Additional importance, also be related to the fact that the integrity of both cysteines residues is essential to rhodanese activity *in vivo*. The necessity of the Cys³³ to cyanide resistance *in vivo* still needs research to the understanding it role to the cell defenses. However, it is interesting to mention that some members of the monothiol Grxs family, including yeast Grx3 and Grx4, were recently shown to form [2Fe-2S]-bridged homodimers using as Fe ligands the active site cysteines residue assisted by two GSH molecules [58]. These unusual GSH-linked Fe-S clusters in monothiol Grxs provide a direct link between iron homeostasis with Fe-S cluster assembly and thiol redox regulation. Finally, by all the arguments presented above, the *glurho* protein may be an important pathogen enzyme involved several strategies for the attack and neutralization of host defenses.

Figure 1 - Sequence alignment of Glurho homologues. The deduced amino acid sequences were obtained at the ncbi genebank (<http://www.ncbi.nlm.nih.gov>), the sequence alignment was performed using the Clustal W2 (www.ebi.ac.uk/Tools/msa/clustalw2) and the alignment scoring and graphical representation was performed using the Jalview (www.jalview.org). Identical residues are shaded in purple and sequence similarities are indicated by a purple gradient based on the conservation of physicochemical characteristics of the amino acids. The abbreviations used to organisms and proteins are as follows: GLP1 – Glurho protein from *X. fastidiosa*; GLP2 – Glutaredoxin-like protein from *X. campestris* pv. *Campestris*; GLP3 – Glutaredoxin-like protein from *X. campestris* *musacearum*; GLP4 – Glutaredoxin-like protein from *X. gardneri*; GLP5 – Glutaredoxin-like protein from *X. vesicatoria*; GLP6 – Glutaredoxin-like protein from *X. Oryzae oryzicola*; GLP7 – Glutaredoxin-like protein from *X. Oryzae oryzae*; GLP8 – Glutaredoxin-like protein from *X. fuscans aurantifoli*; GLP9 – Glutaredoxin-like protein from *X. campestris* pv. *musacearum*; GLP10 – Glutaredoxin-like protein from *X. axonopodis* pv. *citri*; GLP11 – Glutaredoxin-like protein from *X. axonopodis* pv. *punicae*; GLP12 – Glutaredoxin-like protein from *X. citri* pv. *mangiferaeindicæ*; GLP13 – Glutaredoxin-like protein from *X. sacchari*; GLP14 – Glutaredoxin-like protein from *X. albilineans*; GLP15 – Glutaredoxin-like protein from *X. translucens* pv. *graminis*; GLP16 – Glutaredoxin-like protein from *Stenotrophomonas maltophilia*; GLP17 – Glutaredoxin-like protein from *Stenotrophomonas* sp.; GLP18 – Glutaredoxin-like protein from *Pseudomonas geniculata*; GLP19 – Glutaredoxin-like protein from *Pseudomonas spadix*; GLP20 – Glutaredoxin-like protein from *Pseudoxanthomonas suwonensis*; GLP21 – Glutaredoxin-like protein from *Rhodanobacter* sp.; GLP22 – Glutaredoxin-like protein from *Frateuria aurantia*; GLP23 – Glutaredoxin-like protein from *Haliangium ochraceum*; GLP24 – Glutaredoxin-like protein from *Plesiocystis pacifica*; GLP25 – Glutaredoxin-like protein from *Sorangium cellulosum*.

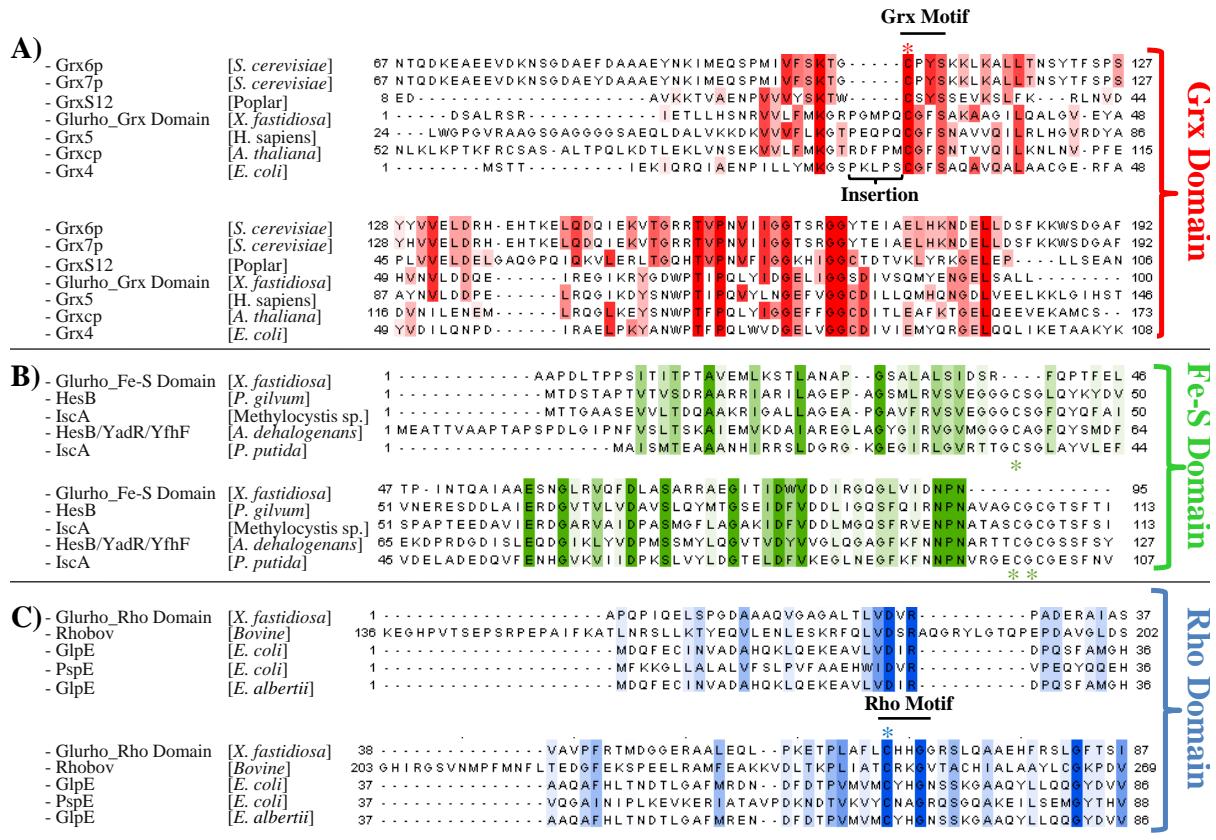

Figure 2 - Similarity analysis of Glurho domains. To perform the analysis the Glurho *X. fastidiosa* deduced amino acid sequence of the protein was divided in three independent segments as defined by the CCD database. Protein sequences of well known Grx, Fe-S cluster assembly and rhodanese representatives were obtained at the ncbi database (<http://www.ncbi.nlm.nih.gov>), the sequence alignment was performed using the Clustal W2 (www.ebi.ac.uk/Tools/msa/clustalw2) and the alignment scoring and graphical representation was performed using the Jalview (www.jalview.org). Identical residues are shaded in red, green and blue, to Grx, Fe-S cluster assembly and rhodanese, respectively. Sequence similarities are indicated by a gradient based of the conservation of physicochemical characteristics of the amino acids. **A)** Alignment of amino acid sequences of monothiol from *S. cerevisiae* (Grx6p and Grx7p), Poplar (GrxS12) *E. coli* (Grx4) *H. sapiens* (Grx5), *A. thaliana* (Grxcp) and Grx domain of Glurho from *X. fastidiosa*. Identical amino acids are highlighted in red and catalytic motif is pointed out (CGFS). **B)** Amino acid sequences alignment of proteins related to Fe-S clusters biosynthesis, *Polymorphum gilvum* (HesB), *Methylocystis* sp. (ISCA), *Anaeromyxobacter dehalogenans* (HesB / YADR / YfhF) and Fe-S_biosynthesis domain of Glurho from *X. fastidiosa*. Identical amino acids are highlighted in green. **C)** Amino acid alignment sequences of *Bos Taurus* Rodanases (Rhobov), *E. coli* (PspE), *E. coli* (GlpE), *E. albertii* (GlpE) and Rho domain of Glurho from *X. fastidiosa*. Identical amino acids are highlighted in blue and catalytic motif is pointed out (CHHG in the case of Glurho). The red, green and blue asterisks highlight characteristic cysteines residues of glutaredoxins, Fe-S assembly proteins and rhodanases, respectively. The black bar near to the Grx motif is relative to the insertion of monothiolic Grx.

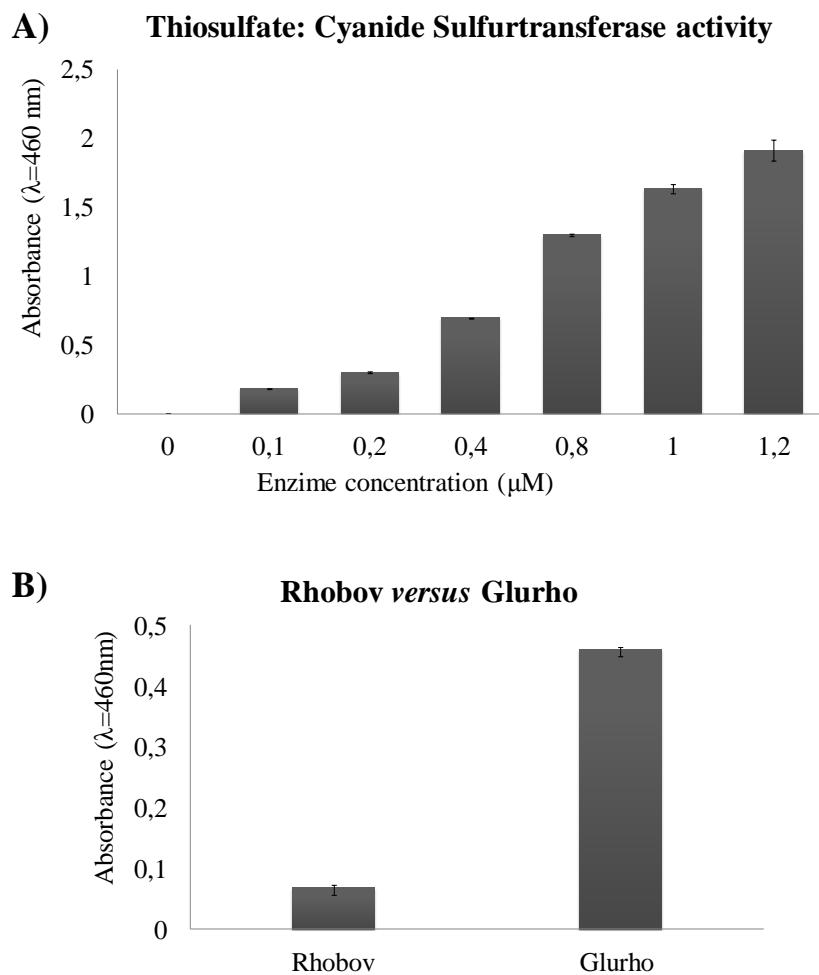

Figure 3 – Evaluation of Glurho rhodanese acyivity. **A)** Determination of Thiosulfate – cyanide sulfurtransferase activity by Glurho. The reactions were performed in 1ml containing 40 mM potassium phosphate, 50 mM cyanide, 50 mM sodium thiosulfate and Milli Q water (q.s.p). The reactions were initiated by adding 0-1.2 μM of the enzyme. After 5 minutes the reaction were stopped by adding formaldehyde 2.5% (300 μl), and then by adding ferric nitrate (100g of $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ and 200 ml of 65% HNO_3) (200 μl). The ferrithiocyanide formation was determinate spectrophotometrically ($\lambda=460\text{nm}$). **B)** Comparative rhodanese activity of Glurho and bovine rhodanese (Rhobov). The reaction was carried out in the same conditions described above for 1min using 1 μM of Glurho or 1 μM of Rhobov. In both assays no enzyme was added to control reactions. All assays were performed in triplicate for three times.

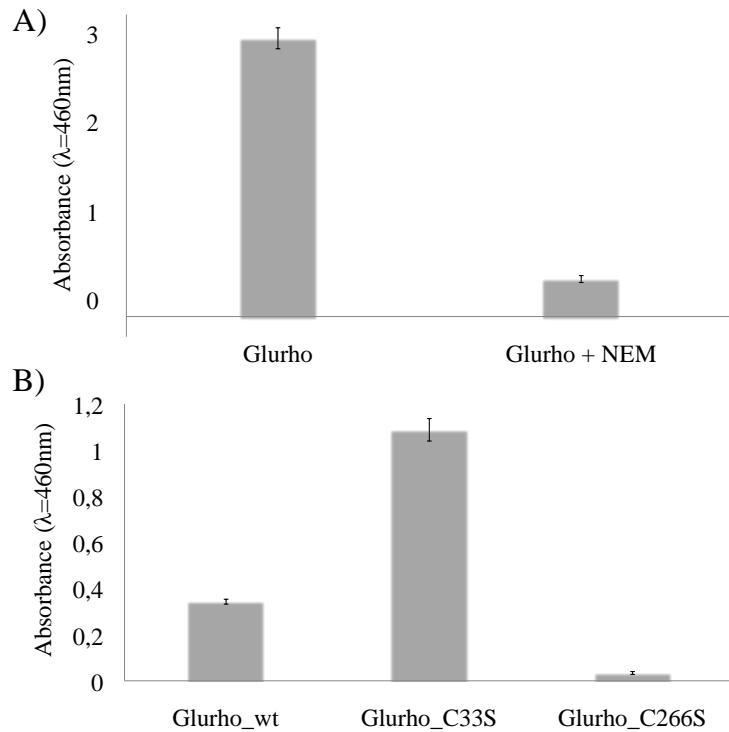

Figure 4 – Involvement of Cys-33 and Cys-266 in Glurho sulfurtransferase activity. **A)** Determination of Glurho^{C33S} and Glurho^{C266S} sulfurtransferase activity. The assays were performed in 1ml containing 40 mM potassium phosphate, 50 mM potassium cyanide, 50 mM sodium thiosulfate and Milli Q water (q.s.p). The reactions were initiated by adding 1 μM of the wild type Glurho enzyme or Glurho^{C33S} and Glurho^{C266S}. After five minutes (the reactions were stopped by adding formaldehyde 2.5% (300 μl), followed by ferric nitrate (100g of $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ and 200 ml of 65% HNO_3) (200 μl). The ferrithiocyanide formation was determinate spectrophotometrically ($\lambda=460\text{nm}$). The assays were performed in triplicate for three times.

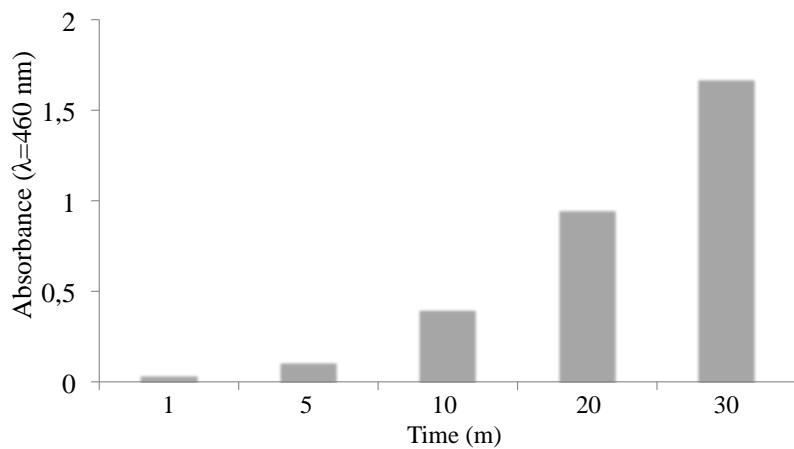

Figure 5 – Evaluation of thiocyanate formation catalyzed by Glurho at different time intervals. The reactions were performed in 1ml containing 40 mM potassium phosphate, 50 mM potassium cyanide, 50 mM sodium thiosulfate and Milli Q water (q.s.p). The reactions were initiated by adding 1 μ M of the Glurho enzyme. After different period of times (1, 5, 10, 20 and 30 minutes) the reactions were stopped by adding formaldehyde 2.5% (300 μ l), followed by ferric nitrate (100g of $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ and 200 ml of 65% HNO_3) (200 μ l). The ferrithiocyanide formation was determinate spectrophotometrically ($\lambda=460\text{nm}$).

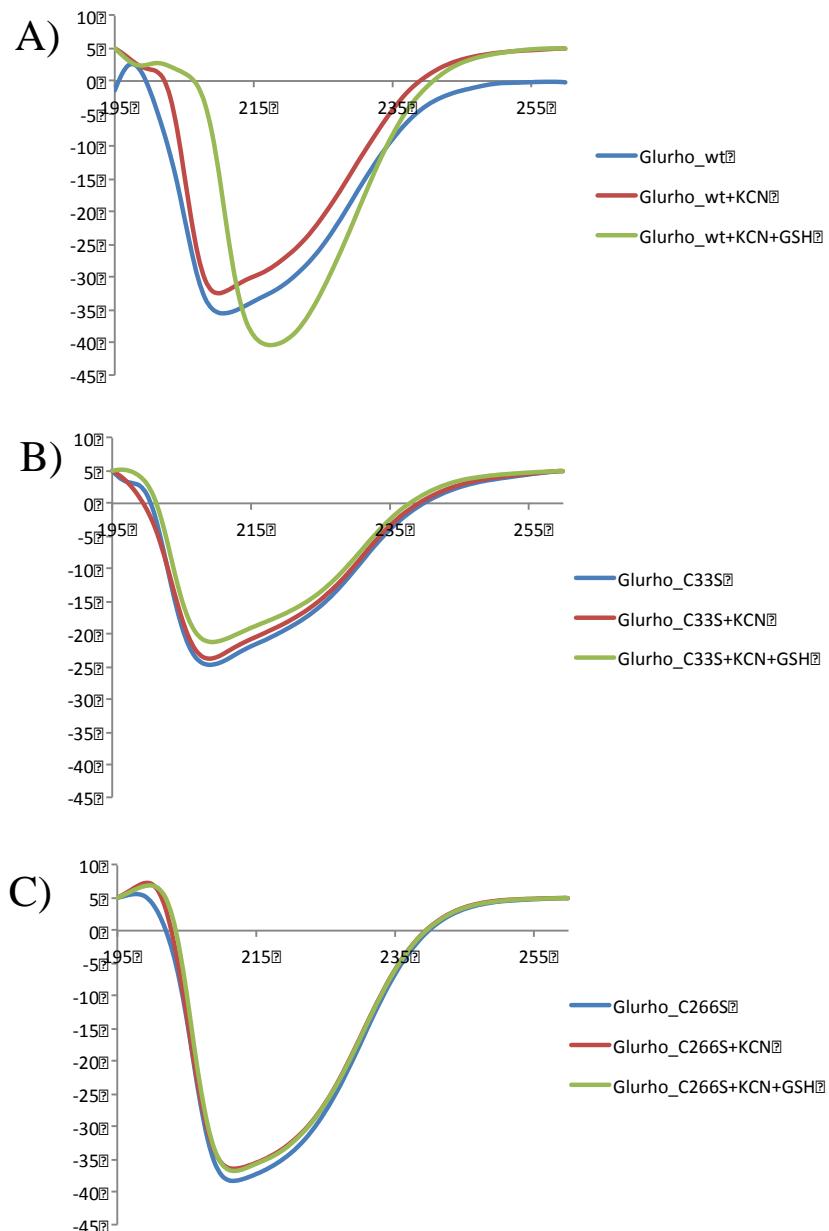

Figure 6. CD spectra of reduced and oxidized samples of Tsa1^{WT} and mutants containing Thr⁴⁴ and Arg¹²³ substitutions. Spectra in the reduced form with 5 mM of TCEP (solid line) and treated with 1.2 eq of hydrogen peroxide (dashed line) of the enzymes Tsa1^{WT} (A), Tsa1^{T44A} (B), Tsa1^{T44S} (C), Tsa1^{T44V} (D), Tsa1^{R123G} (E) and Tsa1^{R123K} (F). The proteins concentration used in experiments were 10 μM in 20 mM sodium fluoride buffer (pH 7.4). All spectra were recorded at 25°C and corrected against the buffer. The graphical representations are averages from eight consecutive scans.

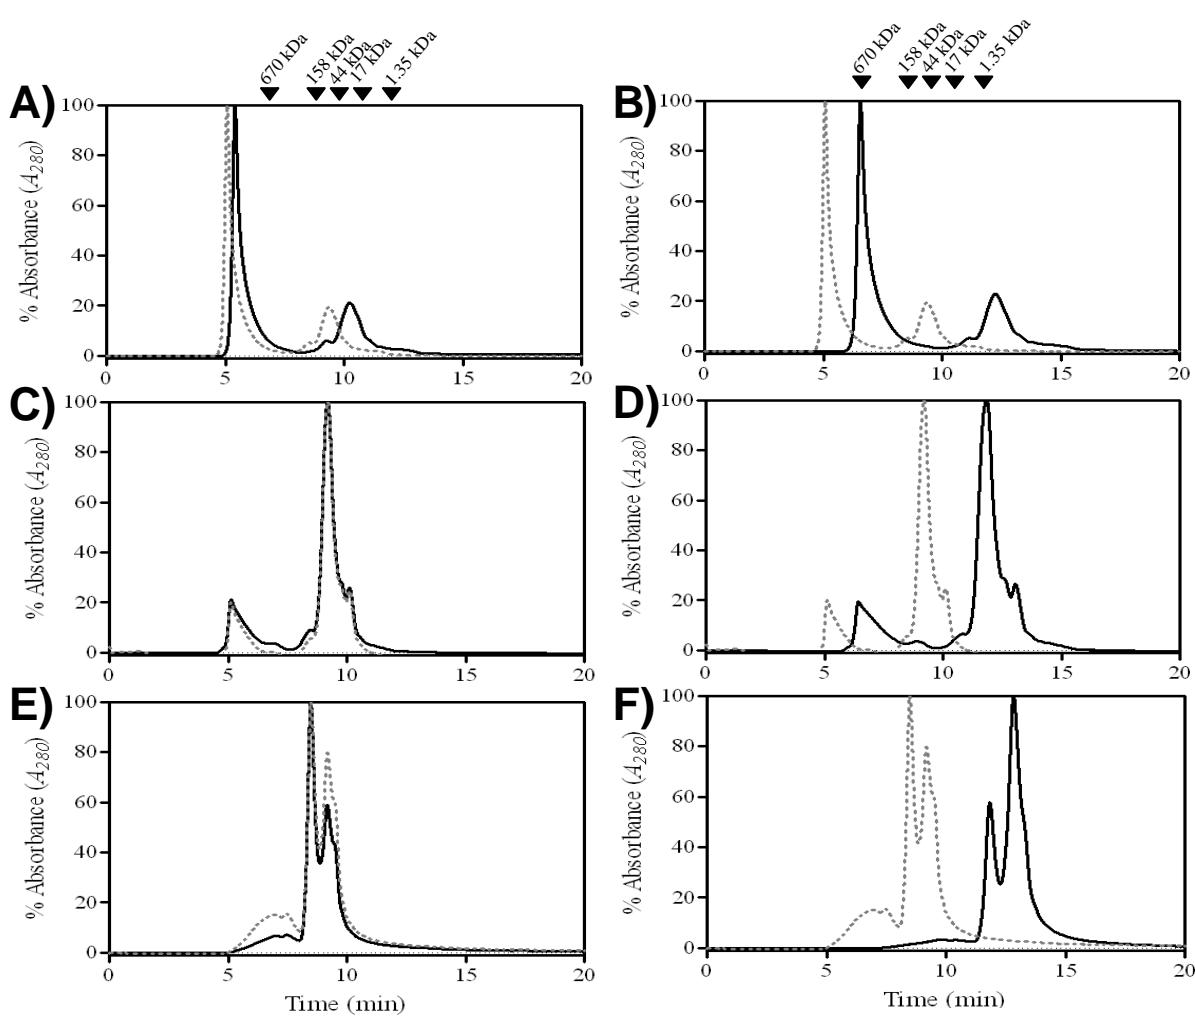

Figure 7. Size-exclusion chromatography - size-exclusion chromatography was performed by analytical hplc using a jasco series equipped with a pu 2880 plus injector and a pda md 2018 detector (jasco). the samples (15 μ mol in 100 mM tris-HCl at pH 7.4) were separated by a system containing a phenomenex biosep-sec-s3000 column (7.8 \times 300 mm, 5 μ m, resolution range of 15 to 2000 kDa, phenomenex, inc., torrance, California, USA) using a flow of 0.5 ml/min in tris-HCl buffer (pH 7.4) and 50 mM NaCl. the elution profile was monitored at a wavelength of 280 nm. bovine thyroglobulin (670 kDa), bovine gamma globulin (158 kDa), ovalbumin (44 kDa), myoglobin (17 kDa) and vitamin B₁₂ (1.35 kDa) were used as molecular standards (bio-rad). the chromatograms were analyzed using the class-vp software (shimadzu co.). the redox treatments for tsa1 and mutant proteins were 5 mM TCEP or 1.2 Molar equivalents of hydrogen peroxide for 2hs/30°C.

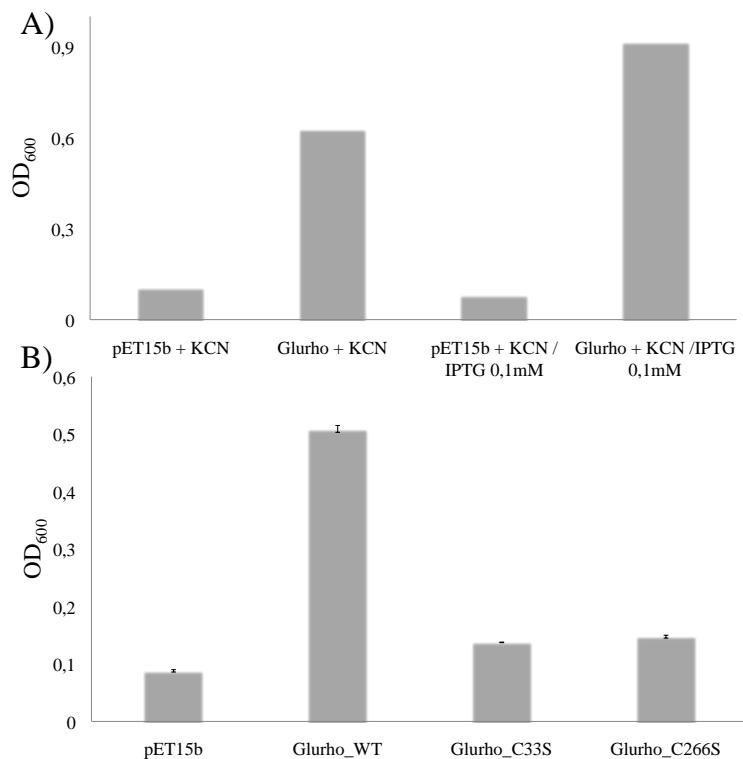

Figure 11 - Only the heterologous expression of intact Glurho protein confers to *E. coli* cells a high resistance to cyanide . A) Cell cultures of *E. coli* BL21 (DE3) containing the empty plasmid (pET15B) or harboring pET15b/Glurho in exponential phase were diluted to OD₆₀₀=0.1, exposed to KCN⁻ (1.3 mM) and grown at 37°C, with the addition or not of IPTG 0.1mM to evaluate the protective effect of basal expression on cell. The growth rate was determined after 24 hs. B) Effects of cysteines substitutions over the cyanide resistance of *E. coli* cells harboring the pET15b/Glurho^{C33S} or pET15b/Glurho^{C266S} plasmids. Comparative resistance of *E. coli* cells containing pET15B, pET15b/Glurho, pET15b/Glurho^{C33S} or pET15b/Glurho^{C266S}. The experimental conditions were the same as presented in (A). All assays were performed in triplicate for three times.

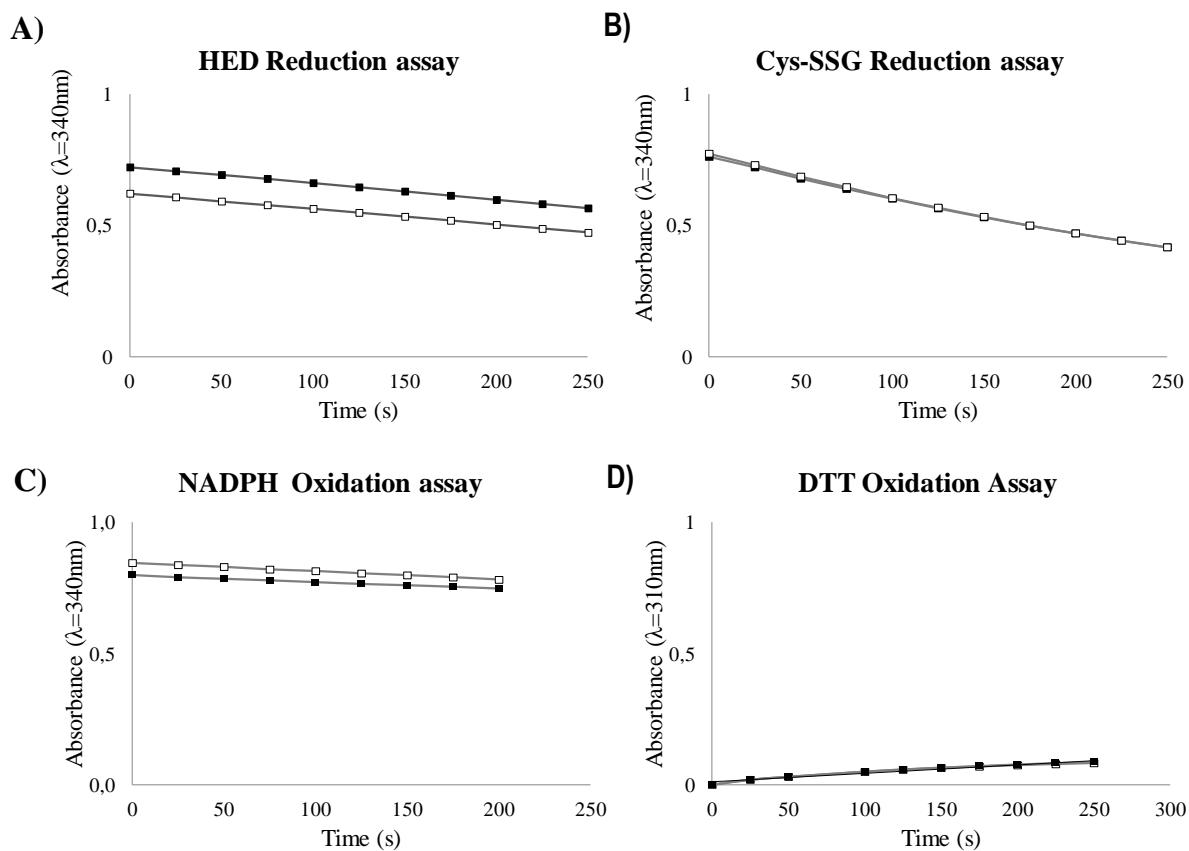

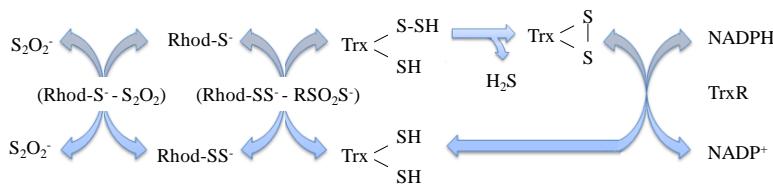

Figure S1 - Evaluation of glutaredoxin activity by different assays. **A) HED assay.** The Glurho ability to reduce the mixed disulfide formed between GSH and β -hydroxyethyl disulfide (HED) was measured spectrophotometrically ($\lambda=340\text{nm}$). The reactions mixtures containing 0.1 M Tris-HCl (pH 7.4); 1mM GSH; 6 $\mu\text{g}/\text{ml}$ GR and 0.7 mM HED were incubated at 30°C for three minutes for the formation of the HED mixed disulfide and then 0.2 mM NADPH was added, the reaction was started by the addition of Glurho and followed by the decrease in the absorbance at 340 nm due to the NADPH oxidation. **B) Cys-SSG reduction assay.** The Glurho ability to reduce the mixed disulfide formed between GSH and Cys was monitored spectrophotometrically ($\lambda = 340\text{nm}$) in 1ml reaction containing: 1mM GSH, Gr 6 $\mu\text{g}/\text{ml}$, 100mM Tris-HCl (pH 7.4), 0.2mM of NADPH, 100 μM of CysS-SG and 1 μM of Glurho. **C) NADPH oxidation assay.** The *t*-BOOH decomposition was measured spectrophotometrically ($\lambda=340\text{nm}$) due to the oxidation of NADPH, the reaction contained: 0.1 M Tris-HCl (pH 7,4); 1mM GSH; 6 $\mu\text{g}/\text{ml}$ GR, 0.2 mM NADPH, 1 μM of Glurho and 1mM of *t*-BOOH. **D) Evaluation of thiol peroxidase activity by DTT oxidation assay.** The H_2O_2 decomposition assay was measured spectrophotometrically ($\lambda=310\text{nm}$), graphic of absorbance \times time was obtained from the DTT oxidation. The reaction contained: 10mM of DTT, 100mM Tris-HCl (pH7.4), 1mM of H_2O_2 and 1 μM of Glurho. The blank squares (□) represent the complete reaction whereas the black squares (■) are relative to the negative controls (with no addition of Glurho). All the experiments were performed using triplicates.

B)

NADPH oxidation Assay - Trx as Sulfur Acceptor

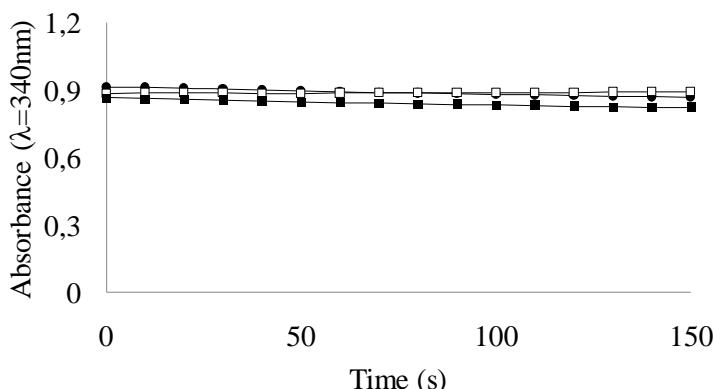

Figure S2 – Evaluation of *E. coli* Trx and *X. fastidiosa* as sulfur acceptor to Glurho. A) Mechanism of sulfur transfer by rhodanases to Trx. Schematic representation of rhodanese sulfur transference from thiosulfate ($S_2O_2^-$) using Trx as acceptor. Initially, the rhodanese captures the sulfur and transfer to the Trx that becomes oxidized and releases a hydrogen sulfide. The oxidized Trx is reduced by the TrxR using NADPH reducing equivalents. B) Glurho NADPH oxidation assay. The evaluation of Glurho uses the protein Trx was monitored spectrophotometrically ($\lambda= 340\text{ nm}$) by the NADPH oxidation assay for 120 seconds. The reaction was performed in 1ml containing: potassium phosphate buffer 50 mM, TrxR (*E. coli*) 0.2 μM , NADPH 150 μM , *X. fastidiosa* Trx (Tsnc) 10 μM or *E. coli* Trx 10 μM , 80 mM of sodium thiosulfate and 10 μM of Glurho. The black circles (●) are relative to the negative control reaction (without Glurho). The black squares (■) are relative to the reaction using *X. fastidiosa* Trx (Tsnc) and white squares (□)the reactions performed with *E. coli* Trx. The assays were performed in triplicate.

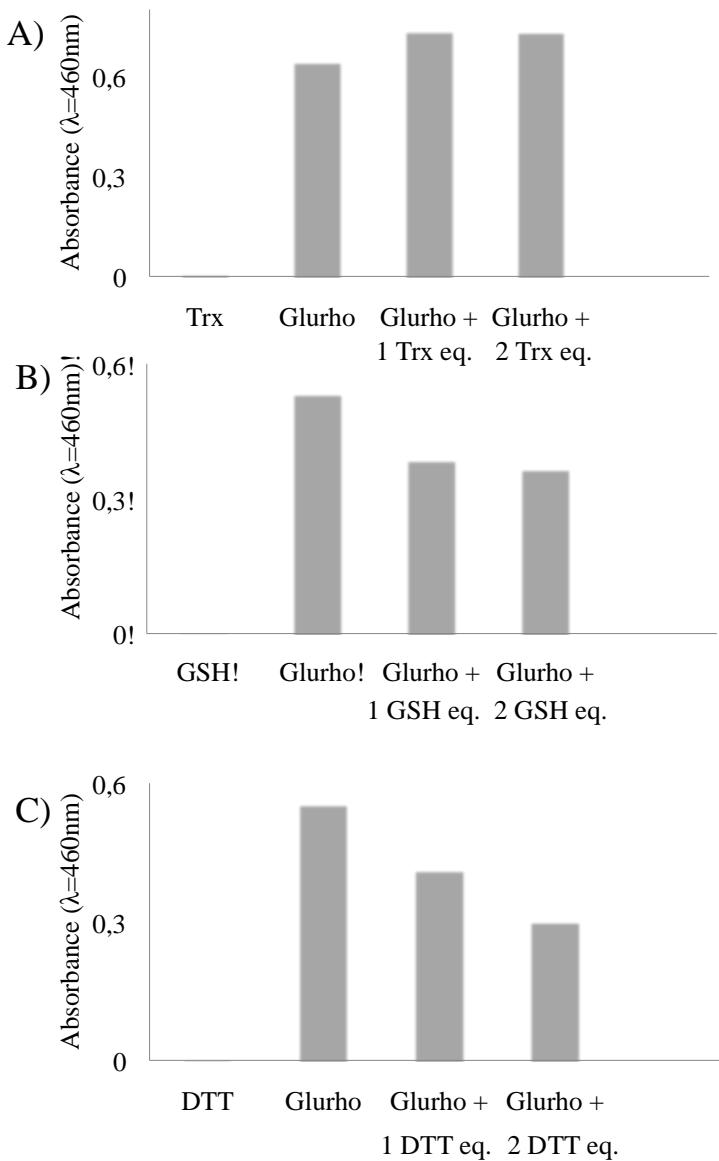

Figure S3 – Evaluation of Glurho sulfur transferase activity to thiolic acceptors. Evaluation of sulfurtransferase activity of Glurho over *X. fastidiosa* Trx (Tsnc) (A) or the low molecular weight thiolic compounds GSH (B) or DTT (C). The reactions were performed essentially as described in Material and Methods to ferrithiocyanide assay. As the positive control just Glurho (1 μM) was added to the reactions and for negative control only the thiolic compounds. The ferrithiocyanide formation was determinate spectrophotometrically ($\lambda=460\text{nm}$). Were tested 1 or 2 molar equivalents of each thiolic compound. The results are representative of three independent experiments.
